ANGIOSTRONGYLUS CANTONENSIS DOUGHERTY, 1946

Introduction

The genus *Angiostrongylus* includes approximately 20 species infective to small mammals, of which two are definitively known to be pathogenic to humans. *A. cantonensis* is inherently neurotropic, causing eosinophilic meningoencephalitis, whereas *A. costaricensis* causes abdominal angiostrongyliasis. *A. mackerrase* may also cause eosinophilic meningitis in Australia. *A. malaysiensis* occurs in South East Asia and three cases of eosinophilic meningoencephalitis might have involved this species (Cross 1987). A comparative study of *A. cantonensis* and *A. malaysiensis* in monkeys revealed that the former was more pathogenic causing fatal infections.

A. cantonensis was first found in rats, a discovery made in China in 1935 (Chen 1935) and in Taiwan 2 years later. Human infection was first confirmed in Taiwan, but its public health importance was not recognized until the parasite was found in the brain of a Filipino patient in Hawaii (Rosen et al. 1962).

Classification and morphology

The genus *Angiostrongylus* belongs to the order Strongylida and the superfamily Metastrongyloidea. Although the genus has now been divided into five, and *A. cantonensis*, *A. costaricensis*, *A. malaysiensis*, and *A. mackerrase* placed in the new genus *Parastrongylus*, *Angiostrongylus* is used for classification here, because most parasitologists still use this terminology.

Adult males measure 20–25 × 0.32–0.42 mm. The buccal cavity has two lateral teeth, but no lips. The esophagus is club-shaped, and measures 0.31–0.32 mm long (Figure 1). There is an excretory pore just posterior to the esophagus. Spicules are slightly subequal in length, and range between 1.02 and 1.25 mm long. The gubernaculum is 0.095 mm long. The bursa and rays are well developed (Figure 1).

Adult females measure 22–34 × 0.34–0.56 mm. The esophagus is 0.35–0.46 mm long. The blood-filled intestine and white uterine tubules are spirally wound in a characteristic 'barber's pole' pattern. The vulva and anus open at distances of 0.19–0.27 and 0.04–0.06 mm, respectively, from the tip of the tail (Figure 1). Eggs measure approximately 70 × 30 μm.

Life cycle

The life cycle in the rat was first described by Mackerras and Sandars (1955). Adult worms live and lay eggs mainly in branches of the pulmonary artery, but sometimes in the right ventricle. Eggs are carried to the lung capillaries where they form emboli. They embryonate and hatch after about 1 week. First-stage (L1) larvae enter alveoli, then migrate up the trachea. They are subsequently swallowed and passed out with feces. In the intermediate host, larvae undergo two molts to the second (L2) and third (L3) stage, after 7–9 and 12–16 days respectively. The L3 larvae are 460–510 μm long and, in molluscan intermediate hosts, remain enclosed in the L1 and L2 sheaths.

Many terrestrial and aquatic snails and slugs can serve as intermediate hosts (Chen 1979; Otsuru 1979). Important snails for transmission are the giant African snail, *Achatina fulica* and *Pila* spp. More recently, another edible snail, *Ampullarium canaliculatus*, was found to be naturally infected in Japan and Taiwan.

Animals that acquire L3 larvae by eating infected mollusks may act as paratenic (transport) hosts and may transmit *A. cantonensis* to humans. Known paratenic hosts are toads, frogs, freshwater prawns, land planarians, and land crabs. The yellow tree monitor has also been described as an epidemiologically important paratenic host in Thailand.

When ingested by rats, L3 larvae exsheathe and penetrate into the intestinal wall, reaching the heart via the portal system and the inferior vena cava. Larvae then reach the left ventricle through the pulmonary circulation. Some migrate to the brain directly, whereas others migrate first through other organs or tissues. In either case, L3 larvae reach the central nervous system (CNS) within 2–3 days, after which they migrate within the brain and grow. The larvae molt twice, to become young adults that migrate through brain tissue to the subarachnoid space. Approximately 26–29 days after infection, the worms, now 11.5–13.0 mm long, penetrate cerebral veins and return to the pulmonary arteries via the heart. The worms now grow rapidly and females lay eggs from around day 35. L1 larvae appear in the feces 40–42 days after infection.

In non-permissive hosts, including man, L3 larvae reach the CNS and molt twice, developing into young adults. They die in the brain without returning to the heart and lungs, causing serious eosinophilic meningoencephalitis.

Although *A. cantonensis* has been recovered from the lungs of four patients, it seems unlikely that it can develop to sexual maturity in immunocompetent humans. Among these four, a fatal case reported by Cooke-Yarborough et al. (1999), was an 11-month-old boy who did not show any cerebrospinal fluid (CSF) eosinophilia and harbored adult *A. cantonensis* in the

lung after having been treated with intravenous methylpredonisolone. Experimentally, young adult worms have been recovered from the heart and lungs of immunosuppressed mice (Yoshimura et al. 1982; Sugaya and Yoshimura 1988; Sasaki et al. 1993), but it is still unclear whether full maturity is reached. The pulmonary migration and maturation of *A. cantonensis* in non-permissive hosts may be associated with the immunocompromised state of the host.

Transmission and epidemiology

A. cantonensis infection can occur at any age, even in young infants (Shih et al. 1992). Humans are infected by the following routes: (1) ingestion of L3 larvae in raw or undercooked intermediate or paratenic hosts; (2) by drinking infected water; and (3) oral contact with hands contaminated with larvae released from mollusks. Infections can be established in rodents by various routes including lacerated, abraded, or intact skin. Theoretically, therefore, humans may also acquire infections through the skin.

In Taiwan, most infections occur in aboriginal children, and are acquired by eating infected giant African snails; 80 percent of cases are in children under 14 years old (Chen 1979). The overall snail infection rate is 28 percent, but snails of size >60 mm show 65 percent infection. Infections also occur in infants in the islands of Reunion and Mayotte (Graber et al. 1997; Edmar et al. 1999). In contrast, infections in Thailand are commonly seen in adult males, who often eat chopped raw *Pila* snails with vegetables as an accompaniment to alcoholic drinks. The overall snail infection rate has been calculated as 20 percent, but it was as high as 73 percent in some areas (Teekhasaenee et al. 1986). Infection generally occurs during the rainy months.

Most of the cases reported in Japan have originated from the Ryukyu Islands, where patients have become infected by eating fresh toad liver or raw slugs as medicines (Otsuru 1979). Freshwater prawns, or sauces containing them, are responsible for infections acquired in the Pacific Islands, while in New Caledonia, infections are linked to accidental ingestion of infected small planarians (or fragments of these) on vegetables (Ash 1976). In Micronesia, land crabs and mangrove crabs act as paratenic hosts (Alicata 1965). L3 larvae shed in slug mucus on lettuce may be a source of human infection in Malaysia (Heyneman and Lim 1967). Initial reports of *A. cantonensis* in rodents and mollusks were restricted to tropical and subtropical areas (Alicata and Jindrak 1970), but it has since been found in many other countries.

Cerebral and ocular infections in humans have been confirmed in Hawaii, Japan, China, Taiwan, Thailand, Vietnam, Malaysia, Indonesia, Vanuatu, American Samoa, and the Ivory Coast (Cross 1987). Confirmed or suspected angiostrongyliasis has also been reported in Australia, Fiji, New Orleans, Sri Lanka, Egypt, Cuba, and Madagascar. Cases are common in Taiwan, Ponape island, Tahiti island, and New Caledonia and thousands of cases occur every year in Thailand. Recently, an outbreak of *A. cantonensis*-associated eosinophilic meningitis was recorded in US tourists returning from Jamaica (Slom et al. 2002) and the enzootic *A. cantonensis* infection in rats and snails was noted in Jamaica (Lindo et al. 2002).

It was previously thought that the spread of *A. cantonensis* was linked to dissemination of the giant African snail (Alicata and Jindrak 1970), but this snail does not occur in many of the new endemic areas. This suggests that if infected rats are present, the life cycle of this parasite may easily become adapted to indigenous mollusks (Cross 1987).

Clinical manifestations

These are primarily associated with meningeal irritation and cerebral damage (Table 1). Symptoms develop 3–36 days after infection.

Severe headache is the most common symptom (occurring in 86–99 percent of patients). It initially occurs intermittently, but later becomes more frequent. Nausea or vomiting, fever (<38°C), constipation, malaise, and anorexia are frequent (Yii 1976). Less common symptoms are cough, neck stiffness, paresthesia, weakness of extremities, muscle twitching, diplopia, strabismus, and facial paralysis. Patients often present with abnormal (usually decreased) tendon reflexes, Kernig's sign, Brudzinski's sign, sometimes with absence of abdominal reflexes and eye muscle paralysis.

The disease is self-limiting and recovery usually occurs within 4 weeks. Serious cases sometimes result in coma, paralysis of the extremities, urinary incontinence or retention, profuse salivation, convulsions, and the persistence of symptoms (Prociv and Tiernan 1987). Fatality ranges from 0.5 percent (Thailand) to 3 percent (Taiwan).

Eosinophilic radiculomyeloencephalitis has been reported, characterized by peripheral and spinal fluid eosinophilia, severe radicular pain, weakness, and hyporeflexia of the legs and dysfunction of the bladder and bowels (Kliks et al. 1982). Patients may exhibit transient hypertension and lethargy and some become comatose. In eosinophilic myelomeningoencephalitis, patients develop a generalized maculopapular rash followed by myalgia, marked paresthesia, fever, and headache, with progressive weakness, particularly of the legs rather than the arms. Some patients may progress to coma and die (Witoonpanich et al. 1991). A long-lasting, chronic intractable pain, refractory to usual pain management, has also been noted in some patients, the pain of whom

was successfully relieved by an implantable spinal cord stimulator (Crump et al. 1999).

Infected mice usually develop paralysis of the extremities, ataxia, circling, and torticollis at around day 20 after infection. They develop degenerative or necrotic Purkinje cells that subsequently disappear from the cerebellum, suggesting a Gordon-like phenomenon (Figure 2) (Yoshimura et al. 1988, 1994). Eosinophils in the spinal fluid and those around degenerating worms exhibit degranulative changes (Figure 3). Eosinophil peroxidase has been detected in the spinal fluid of infected guinea pigs (Perez et al. 1989). Therefore, neurological disorders in eosinophilic meningoencephalitis are probably due not only to mechanical damage caused by migrating worms, but also to the neurotoxicity of eosinophil-derived basic proteins.

Ocular angiostrongyliasis has been reported from Thailand, Taiwan, Vietnam, Indonesia, Japan, Papua New Guinea, and Sri Lanka, worms being found in the anterior chamber, retina, and other sites. This form is rarely accompanied by meningoencephalitis (Nelson et al. 1988). L3 larvae migrate to the base of the brain, move anteriorly into the orbit and finally penetrate the eye via the cribriform plate (Teekhasaenee et al. 1986). Intracerebral migration may also cause optic nerve injury. Worms measuring 500 μm–18.6 mm have been found in the anterior chamber, vitreous humor, and posterior pole of the eye, provoking a variety of symptoms (Scrimgeour et al. 1982; Teekhasaenee et al. 1986). Blindness may develop in rare cases.

Pathogenesis and pathology

Parasites, usually young adult worms, are found mostly in the medulla, pons, and cerebellum and in the adjacent leptomeninges (Jindrak 1975) (Figure 4). Some worms are alive at post-mortem, whereas others are disintegrating. The number of worms varies, but may reach several hundreds. Reactions are rarely seen around live worms, but dead worms are often surrounded by infiltrates of polymorphs and eosinophils, or by a zone of suppurative necrosis or granulomatous tissues. Migrating tracks (infiltrates of macrophages, foreign-body giant cells, plasma cells, eosinophils) are found near to worms and at some distance away. Nerve cells near tracks show central chromatolysis and cytoplasmic axonal swelling and blood vessels show perivascular cuffs of eosinophils, lymphocytes, and plasma cells.

The leptomeninges are infiltrated with leukocytes, infiltration being marked over the cerebellum, pons, and medulla. Worms are commonly seen within the underlying nerve tissue and the vessels, particularly veins, are dilated. The subarachnoid space is widened. Worms are found on the surface of the pia mater and foreign-body giant cells are found in the subarachnoid space near to parasites, as well as more remotely. Cases of eosinophilic radiculomyeloencephalitis show a markedly swollen brain, intensely engorged meningeal vessels, and diffuse subarachnoid hemorrhage. Numerous worms are found in sections of the spinal cord, but not the brain

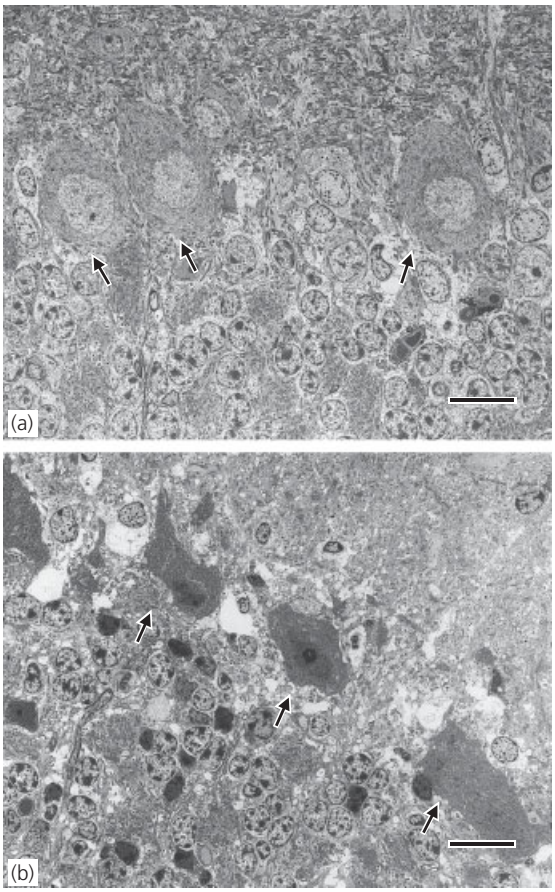

Figure 2 *Purkinje cells (arrows) of the cerebellum from a normal ddY mouse* **(a)** *and from an infected ddY mouse at 25 days after infection* **(b)**. *Purkinjé cells in the infected mouse are small and irregular shaped, with pyknotic nuclei. Bar, 10 μm*

Eosinophils show marked degranulative changes, i.e. loss of matrix material from specific granules (arrowheads). Bar, 2 μm*

(Kliks et al. 1982). The most striking findings are multiple hemorrhage tracks and cavities caused by worms migrating in the brain parenchyma and spinal cord (Witoonpanich et al. 1991).

Diagnosis

Eosinophilic pleocytosis (Table 2) and a history of eating mollusks are indicative. Spinal fluid eosinophilia develops at around day 12 after infection, peaking at days 25–30 (Punyagupta et al. 1975). Opening pressure is raised to >200 mm H_2O. Spinal fluid is usually clear or slightly cloudy, but not xanthochromic (Table 2). The white blood cell count in the fluid range from 150 to 2 000/μl, of which eosinophils exceed 10 percent in 95 percent of patients and usually represent 20–70 percent of the total white cells (Weller 1993). Protein is slightly elevated, but glucose is normal (Table 2).

Diagnosis should not depend on the identification of larvae in spinal fluid; among 257 cases in Taiwan, worms were found in only 25 patients (Chen 1979). Worm recovery is improved if patients sit upright for some time before sampling (Cross 1987).

According to Punyagupta et al. (1975), most patients had peripheral eosinophilia >10 percent and 43 percent showed eosinophilia of 21–50 percent. Blood eosinophilia did not correlate with cerebrospinal fluid eosinophilia or with the clinical course. Over half of patients (56 percent) showed leukocytosis >10 000/mm^2. Chest X-ray findings are normal (Koo et al. 1988). Recently, Graber et al. (1999) noticed the presence of enlarged ventricles and cerebral subarachnoid spaces in computed tomography findings of severe eosinophilic meningitis in infants. Meanwhile, Kanpittaya et al. (2000) suggest a diagnostic value of magnetic resonance imaging (MRI); abnormal findings on MRI of eosinophilic meningoencephalitis include dilated perivascular space, subcortical enhancing lesions, and abnormal high T2 signal lesions in the periventricular regions. Another MRI study showed multiple small high intensity areas on contrast-enhanced T1-weighted images, suggesting tissue reactions to dead or dying worms, and local vasodilatation associated with minimal thrombus formation (Ogawa et al. 1998).

Many serological tests have been used to support the diagnosis (Koo et al. 1988). With partially purified antigens, enzyme-linked immunosorbent assay (ELISA) detects significantly higher IgM and IgE levels in serum than in the spinal fluid (Yen and Chen 1991). Immunoblot analyses for detecting serum antibodies to 31 and 29 kDa female worm antigens are also useful (Akao et al. 1992). More recently, the detection of IgG4 antibody to 29 kDa antigen from young adult worms by immunoblotting was found to be most reliable for discriminating between human angiostrongyliasis cantonensis, gnathostomiasis, and cysticercosis (Intapan et al. 2003). Tests are sometimes complicated by possible cross-reactions between *A. cantonensis* and other nematodes. A

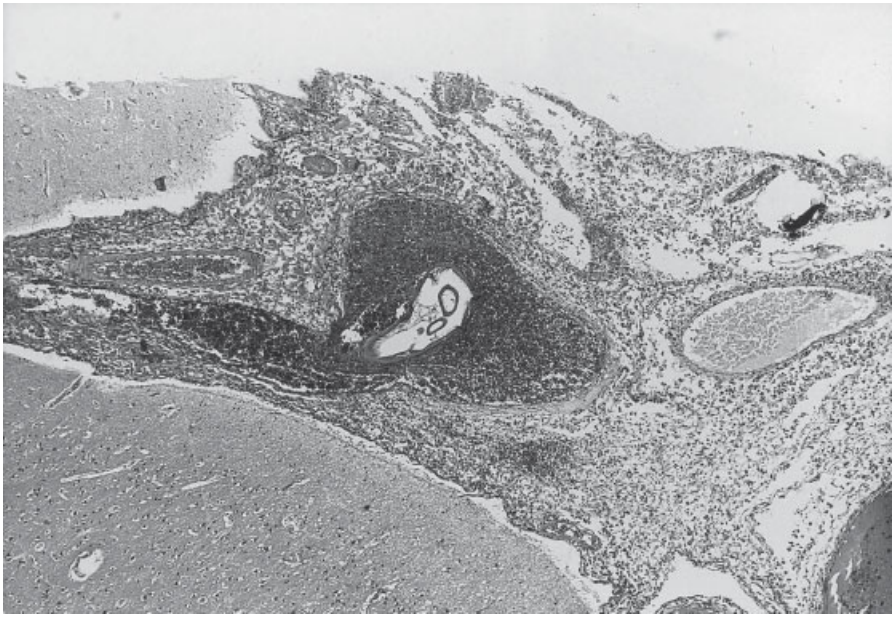

Figure 4 *Cross-section of* Angiostrongylus cantonensis *in a blood vessel of the subarachnoid space of a human patient (×47).*

purified 204-kDa (Chye et al. 2000) and 31-kDa (Eamsobhana et al. 2001) antigen with high specificity and sensitivity improved the accuracy of specific immunodiagnosis by ELISA. Shih and Chen (1991) described two monoclonal antibodies that recognize a 91 kDa antigen in excretory-secretory (E-S) products of L3 larvae, and they used an enzyme-linked fluorescent assay to detect circulating antigen in the serum and cerebrospinal fluid. A simple agglutination test using gelatin particles as an antigen carrier is also useful for detecting *A. cantonensis* antibodies in routine immunodiagnosis (Eamsobhana et al. 1999).

Cerebrospinal fluid eosinophilia often occurs in other helminth infections. In Thailand, it is especially important to distinguish between cerebral and ocular angiostrongyliasis, gnathostomiasis, and cysticercosis, all of which are endemic (Teekhasaenee et al. 1986).

Control

Thiabendazole and levamisole have been used to treat eosinophilic meningitis, but their effectiveness is still doubtful. Symptoms may worsen during treatment (Bowden 1981) and anthelminthics should be used with caution, as most of the pathogenesis is ascribed to dead or dying worms (Cross 1987). Corticosteroids may alleviate some symptoms of increased intracranial pressure and relieve allergic reactions. Lumbar puncture may

Table 2 *Differential diagnosis of cerebrospinal fluid from patients with angiostrongyliasis cantonensis or gnathostomiasis spinigera*

	Angiostrongyliasis (five cases)	Gnathostomiasis (39 cases)
Color	Clear or slightly cloudy	Slightly turbid, xanthochromic, and bloody

Opening pressure (mm)	Increased 210–360 (280)	Increased 90–350 (200)

Data from Schmutzhard et al. (1988)
a) Range (mean)

relieve severe headache. Treatment of ocular angiostrongyliasis depends on surgical removal of the parasite. A 2 percent isoptocarpin solution may prevent the worm from entering the deeper parts of the eye (Widagdo et al. 1977).

In order to prevent disease, ingestion of infected hosts and water or vegetables contaminated with L3 larvae must be avoided. Larvae are killed by freezing at −15°C for >12 h or by boiling for 2–3 min (Alicata 1967). The practice of eating toads or slugs for medical purposes (Otsuru 1979) should be prohibited. Controlling the spread of infected rats and mollusks to areas currently free of *A. cantonensis* will restrict further spread of the parasite. Trends towards increased travel, importation of food, and movement of refugees from endemic areas are all factors which suggest that awareness of this infection must be raised.

ANGIOSTRONGYLUS COSTARICENSIS MORERA AND CÉSPEDES, 1971

Introduction

A. costaricensis was discovered in the mesenteric arteries of patients in Costa Rica by Morera and Céspedes (1971), who established it as the cause of abdominal angiostrongyliasis. It has subsequently been reported from Latin America, USA and, more recently, from Africa (Baird et al. 1987). In humans, adult worms lay eggs that can embryonate, but not hatch. *A. costaricensis* therefore seems to be more adapted to humans than *A. cantonensis*, because it attains sexual maturity (Morera and Céspedes 1971).

Morphology

A. costaricensis lacks a buccal capsule and the excretory pore is located slightly posterior to the esophago-intestinal junction (Morera 1973). Adult males measure 17.4–22.2 × 0.28–0.31 mm. The club-shaped esophagus is 0.182–0.225 mm long. Spicules are of equal length, measuring 0.318–0.330 mm. The gubernaculum has two branches, the bursa is symmetrical and well developed. Behind the cloaca are three papillae (Figure 5). Adult females measure 28.2–42.0 × 0.322–0.35 mm and the esophagus is 0.23–0.26 mm long. The anus measures 0.060–0.065 mm and the vulva is situated 0.24–0.29 mm from the tip of the tail. The uterine tubules arise near the esophago-intestinal junction and spiral around the intestine.

Life cycle

Although the cotton rat, *Sigmodon hispidus*, is the most important natural final host in Costa Rica, 11 additional rodents can also carry infection. Coati-mundi, marmosets, and dogs can also serve as final hosts (Morera 1985; Brack and Schröpel 1995). In Brazil, small rodents other than cotton rats are important final hosts (Graeff-Teixeira et al. 1990). L1 larvae from the final hosts enter slugs, develop to the L3 stage, and are frequently shed into the mucus (Morera 1973). The most important intermediate host in Costa Rica, Ecuador, and Nicaragua is the slug *Vaginulus plebeius*, with infection rates reaching 85 percent (Morera 1985; Duarte et al. 1992). Other mollusks are also susceptible; for instance, in southern Brazil, *Sarasinula linguaeformis* shows a high

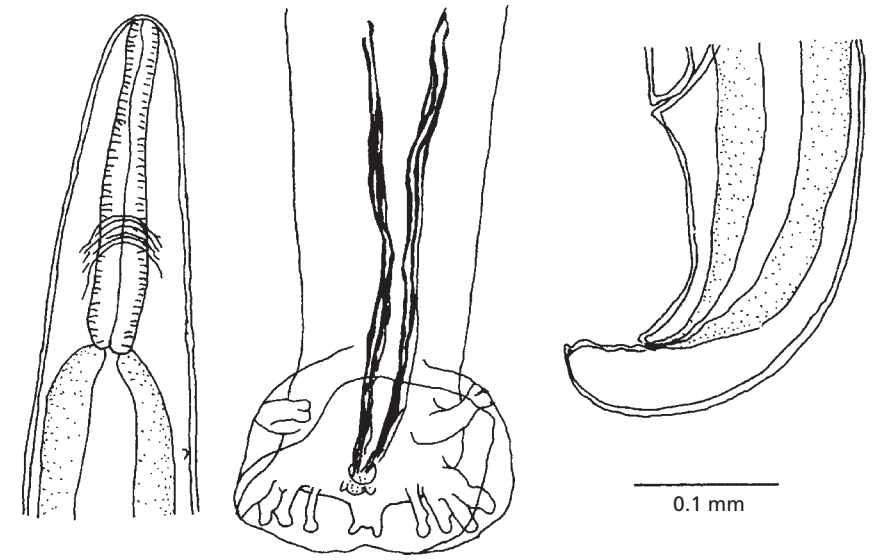

Figure 5 Angiostrongylus costaricensis. **(a)** *Anterior end of the body.* **(b)** *Posterior end of male, showing spicules and bursa.* **(c)** *Posterior end of female, showing rectum and vulva (adapted from Ohbayashi 1979)*

prevalence (86 percent) and individual parasitic burdens (Laitano et al. 2001).

When cotton rats ingest infected slugs, the larvae penetrate the intestinal wall and migrate to the lymphatics. They complete their molts within 7 days. Young adult worms (measuring 3.8–4.4 mm long) migrate to the mesenteric arteries by day 10 and reach maturity and release eggs from day 18. Eggs deposited in the intestinal wall develop and hatch, the L1 larvae appearing in feces 24 days after infection (Morera 1973).

More recently, a new migratory pathway of *A. costaricensis* has been proposed, using the mouse as a definitive host (Mota and Lenzi 1995). The pathway consists of two vascular routes: one is the lymphatic/venous/arterial pathway and the other is the venous portal pathway. The presence of larvae in the lung and liver, especially in the portal veins, of human patients can be accounted for by this new pathway. Moreover, the dog may be a potential reservoir host for *A. costaricensis*, since an experimentally infected dog shed L1 larvae into the feces (Rodriguez et al. 2002).

Transmission and epidemiology

Transmission to humans occurs by ingesting infected slugs, either intentionally or by the accidental ingestion of slugs hidden on vegetables. Larvae shed by slugs can also contaminate hands and food items. L3 larvae can enter abraded (but not unabraded) skin of the cotton rat (Ubelaker et al. 1981).

A. costaricensis is widespread in the American continent, from the USA to northern Argentina. Human infections have been reported from southern Mexico to Argentina. Incidence is particularly high in Costa Rica, numbering some 650 cases annually, or 18 cases/100 000 inhabitants (Morera 1994). Infection is twice as frequent in males as females and occurs predominantly in children under 13 years (99 percent of cases), especially in wet months (Loría-Cortés and Lobo-Sanahuja 1980). In Brazil, the incidence of infection is still increasing.

Clinical manifestations

Symptoms are localized in the abdominal regions, the parasite usually being present in the ileo-cecocolic branches of the anterior mesenteric artery (Morera 1985). Clinical manifestations appear approximately 14 days after infection. Most patients complain of abdominal pain in the right iliac fossa and right flank, and palpation and rectal examinations are painful. Fever lasting for 2–4 weeks is common. Occasionally anorexia, vomiting, diarrhea, and constipation are seen. Patients usually show palpable tumor-like masses in the lower right quadrant and these are often confused with malignant tumors. Hematologically, there is significant leukocytosis and eosinophilia (Table 3). The fatality rate ranges from 1.7 to 7.4 percent (Loría-Cortés and Lobo-Sanahuja 1980; Graeff-Teixeira et al. 1991).

Radiology usually reveals abnormalities in the terminal ileum, cecum, and ascending colon. Contrast medium demonstrates spasticity, filling defects, and irritability at the cecum and ascending colon. Fluoroscopy shows Stierlin's sign. The intestinal lumen becomes narrow. When the liver is affected, pain is localized in the upper right quadrant and hepatomegaly is noticeable. Leukocytosis and eosinophilia are usually higher when there is liver involvement than in the intestinal form of the disease, and liver enzymes may be elevated.

Table 3 *Frequency of clinical symptoms and signs in patients with abdominal angiostrongyliasis*

	No. of cases (%)	
	(116 Costa-Rican cases)	(13 Brazilian cases)
Symptom/sign	Loría-Cortés and Lobo-Sanahuja (1980)	Graeff-Teixeira et al. (1991)

Hepatomegaly	3 (3)	–
Testicular tumor	1 (1)	–
Jaundice	1 (1)	–

Pathogenesis and pathology

Pathogenesis is attributed either to adult worms in the mesenteric arteries or eggs in the intestinal wall (Morera 1985). Worms damage arterial endothelia, causing thrombosis and distal necrosis. In humans, eggs fail to hatch, but provoke local inflammatory reactions with numerous eosinophilic granulomas and ulceration, causing necrotic lesions and thickening of the intestinal wall. The intestinal lumen becomes narrow and restricts passage of fecal material. Additionally, gangrenous ischemic enterocolitis (Vazquez et al. 1993), eosinophilic ileitis with perforation (Wu et al. 1997), and more rarely, jejunal perforation (Waisberg et al. 1999) have been described.

Hepatic lesions are produced by larvae that invade the peritoneal cavity and migrate to reach branches of the hepatic artery. Larvae cause thromboses and the subsequent inflammation destroys the arterial walls (Vazquez et al. 1994). Ectopic infection in the liver may also occur (Morera 1985). Adult worms may block the testicular arteries and cause extensive necrosis (Ruiz and Morera 1983).

Diagnosis

Diagnosis is difficult, because L1 larvae are not discharged in stools. In endemic areas, physicians must pay special attention to appendicitis-like symptoms in children with prominent eosinophilia. Serological tests have been employed, including ELISA and latex agglutination. More recently, a parasite-specific IgG ELISA has been shown to be useful for the diagnosis of the acute phase of the disease (Geiger et al. 2001). Radiological findings of a mass in the right lower quadrant, thickening of the intestinal wall at the ileo-cecal region, and a narrowed intestinal lumen are also suggestive (Loría-Cortés and Lobo-Sanahuja 1980). Definitive diagnosis depends on the examination of biopsy specimens or surgical resections.

Control

Surgical treatments are generally required for definitive cure, but mild disease may resolve spontaneously (Graeff-Teixeira et al. 1987). The following chemotherapeutic regimens are recommended: (1) thiabendazole in combination with diethylcarbamazine; (2) thiabendazole alone; or (3) high-dose mebendazole.

Prevention is the best management. Children in endemic areas must wash their hands before eating. Inspection and thorough washing of vegetables and related foods before consumption are recommended.

In Guatemala, raw mint, frequently eaten separately or as an ingredient of ceviche, is the most likely vehicle of infection (Kramer et al. 1998). Meanwhile, infective larvae become significantly inactive when they are incubated at 5°C for 12 h in solutions of saturated sodium chloride, vinegar or 1.5 percent sodium hypochlorite (Zanini and Graeff-Teixeira 1995). When the larvae are incubated in tap water in a refrigerator at 5°C, however, it will take 80 days to inactivate all the larvae (Richinitti et al. 1999).

TERNIDENS DEMINUTUS RAILLIET AND HENRY, 1909

Introduction

Ternidens deminutus is found in southern Africa, where it infects the large intestines of primates (baboon, vervet monkey, humans), and in parts of Asia where it has been reported only in monkeys.

Classification and morphology

This genus belongs to the order Strongylida, and the superfamily Strongyloidea. Adult males measure 6–13 mm long, and adult females are 9–17 mm. There is a buccal capsule with three deep-set teeth and a mouth with a mouth-collar. The anterior end has four submedian papillae and two lateral amphids. Males have cup-shaped copulatory bursa, two spicules, and a gubernaculum. Females have protuberant vulva slightly anterior to the anus. The eggs are frequently misdiagnosed as hookworm eggs (and hence are known as 'false hookworm'), but their measurements (81.5 × 51.8 μm) are slightly larger (Goldsmid 1968). The L3 larva has paired sphincter cells at the esophageal-intestinal junction.

Life cycle

Eggs hatch into L1 larvae in 2–3 days. Subsequently, they molt to L2 larvae in 2–3 days and to L3 filariform larvae in 8–10 days (Goldsmid 1971).

Transmission and epidemiology

Infection is by oral ingestion of L3 larvae. Cases have been noted in Comoros, Mauritius, and southern Africa, from the Congo to the Republic of South Africa. A maximum prevalence of 87 percent was recorded in Rhodesia (Rogers and Goldsmid 1977). Fecocultures of Bush-negroes in Suriname revealed that two (0.2 percent) of 431 positive fecal cultures were positive for *Ternidens* sp. L3 (Jozefzoon and Oostburg 1994).

Clinical manifestations and pathology

L3 larvae penetrate the mucosa of the large intestine and molt, the L4 larvae producing nodules or ulceration. L4 larvae then molt to the adult stage. If worm loads are

heavy, anemia might result, although *T. deminutus* was not considered to be a blood sucker by von Boch (1956).

Diagnosis

T. deminutus and hookworm L3 can be differentiated morphologically, or by egg volume (Goldsmid 1968). An indirect fluorescent antibody test, using frozen sections of adult worms has been used to distinguish *T. deminutus* from hookworm infections (Rogers and Goldsmid 1977).

Control

Thiabendazole and albendazole give cure rates of >90 percent (Goldsmid 1972; Bradley 1990). Accidental ingestion of the third stage infective larvae should be avoided.

OESOPHAGOSTOMUM SPECIES

Introduction

Although principally parasitic in the large intestines of ruminants and swine, some species of *Oesophagostomum* parasitize monkeys and apes. Larvae produce nodules in the intestinal wall and cause diarrhea, anemia, and intussusception. Human esophagostomiasis occurs predominantly in Africa, with some cases reported in Indonesia, China, and South America. Five species are known in humans (Polderman et al. 1991), *O. bifurcum* being the most common in Africa and Asia (Blotkamp et al. 1993). *O. aculeatum* occurs in South East Asia.

Classification and morphology

This genus belongs to the order Strongylida and the superfamily Strongyloidea. *O. bifurcum* has a mouth surrounded by an oral collar. The cephalic end has a ventral groove and an excretory pore and the club-shaped esophagus is 0.58–0.63 mm long. Adult males measure 8.6–15.1 mm long. The copulatory bursa is trilobate, the dorsal lobe small. Spicules are 1.02 mm long, and a gubernaculum is present. Adult females are 11.0–16.8 mm long. The vulva and anus are located 0.36–0.62 mm and 0.17–0.26 mm, respectively, from the tip of the tail. Eggs measure 58–69 × 39–47 μm, and are indistinguishable from *Necator americanus*.

Life cycle

Eggs develop to the L1 stage in 1 or 2 days at 30°C. The larvae molt twice in 7 days to produce the L3 stage (712–950 μm) which has triangular intestinal cells and a very long, finely tapered tail of the sheath.

Infection occurs by oral ingestion of L3 larvae, which produce nodules in the large intestine wall. After further development, they return to the intestinal lumen, attach to the mucosa, and develop into adult worms. Eggs are discharged in the feces.

Transmission and epidemiology

Oral infection is the most likely route, but infection through the skin is also possible (Ross et al. 1989). *O. bifurcum* L3 are resistant to desiccation and freezing (−15°C for 24 h), implicating the possibility of dust-borne infections in sub-Sahelian areas like northern Togo and Ghana (Pit et al. 2000). Nevertheless, the transmission of infection appears to be limited to the rainy season.

The prevalence of *O. bifurcum* in northern Togo and Ghana has been calculated as 14.2 percent in males and 20.1 percent in females (Polderman et al. 1991). Infection was epidemic in 38/43 villages and prevalence was high (up to 59 percent) in small isolated villages. Infection was rare in children <5 years old, but high levels were found in individuals >5 years old (Krepel et al. 1992). Pit et al. (1999) estimated that more than 100 000 people in Togo were infected with *O. bifurcum*, and actually, infections were more prevalent in women than in men. Likewise, in northern Ghana and Togo, *O. bifurcum* infects an estimated 250 000 people, as determined by cultures of stool samples (Storey et al. 2001).

Clinical manifestations and pathology

L3 larvae penetrate the intestinal wall and produce a solitary, tumor-like inflammatory mass or abscess (helminthoma), measuring one to 2 cm. This is usually located in the ileo-cecal region, but can be present in other organs and in the abdominal wall. The presence of a helminthoma and abdominal pain are major symptoms of the disease. Multiple abdominal masses or nodules containing grayish-green pus and a single immature worm may be present. Intense rectal bleeding and subsequent anemia have been recognized but most cases are totally asymptomatic (Ross et al. 1989).

The clinicopathology has two distinct forms. The multinodular form comprises hundreds of small nodules within a thickened, edematous wall of the large intestine, presenting with weight loss, persistent mucus diarrhea, diffuse abdominal pain, and occasionally, rectal bleeding. Urgent surgery may be required for luminal narrowing of the colon, or bowel obstruction secondary to inflammatory adhesions. On the other hand, the uninodular form, called the Dapaong tumor (Figure 6), presents as a painful 30–60 mm granulomatous mass in the abdominal wall or within the abdominal cavity, often associated with fever (Polderman and Blotkamp 1995; Storey et al. 2000a). Ultrasonography is helpful for diagnosis of these two forms; multinodular disease shows nodular ‘target’ and ‘pseudokidney’ colonic lesions,

Figure 6 *Dapaong tumor resulting from* Oesophagostomum bifurcum *infection (courtesy of Mr P.A. Storey and* Oesophagostomum *research group of Parasitology Department, Leiden University Medical Center)*

whereas the Dapaong tumor is an echo-free ovoid lumen enveloped within a well-defined, poorly reflective wall (Storey et al. 2000a). An epidemiological study in northern Ghana indicates that 13 percent of the cases were multinodular disease, evenly distributed throughout all age-groups, while 87 percent were Dapaong tumor, especially predominant in 5–9-year-old children (Storey et al. 2000b). Oesophagostomes occasionally produce subcutaneous nodules caused by direct skin penetration of L3 larvae or by vascular dissemination of larvae from the bowel (Ross et al. 1989).

Diagnosis

Clinical diagnosis is not necessarily easy and oesophagostomiasis has frequently been misdiagnosed as carcinoma, appendicitis, amoeboma, and other etiologies. Although principally a self-limiting disease, unnecessary radical surgery has frequently been performed. Leukocytosis and blood eosinophilia are not very useful and diagnosis can often be made only by laparotomy (Barrowclough and Crome 1979).

Barium enema examination is useful for detecting a filling defect on the mucosal surface of the large intestine. Harada-Mori test-tube culture technique is used to obtain L3 larvae for morphological identification. A two-step, semi-nested polymerase chain reaction (PCR) method for the specific amplification of minute amounts (fg) of *O. bifurcum* DNA from human fecal samples has been established using genetic markers in the second internal transcribed spacer of ribosomal DNA (Verweij et al. 2000).

ELISA for worm-specific IgG4 antibody has a specificity of >95 percent (Polderman et al. 1993). Body wall and internal structures help to identify worms in histological sections.

Control

Albendazole and pyrantel pamoate give cure rates >80 percent (Krepel et al. 1993). The effect of the drugs on the tissue-dwelling stages is unknown. Accidental oral ingestion of L3 larvae should be avoided.

TRICHOSTRONGYLUS SPECIES

Introduction

At least ten trichostrongylid species are capable of parasitizing humans. Most species are normally found in herbivores, human infections being accidental, but most *T. orientalis* infections have been recorded in humans. Human infections are prevalent in Iran.

Classification and morphology

This genus belongs to the order Strongylida, superfamily Trichostrongyloidea. The worms are minute and delicate, measuring approximately 4–8 mm long. The head is unarmed and lacks a distinct buccal capsule. The male bursa has long lateral dorsal rays that are poorly developed. Spicules are yellowish-brown, stout, and their chrysanthemum-flower-leaf shape is useful for species differentiation. A gubernaculum is present. The female vulva is situated midway along the body. Eggs resemble hookworm ova, but are longer and narrower (measuring 75–91 × 39–47 μm), with one end more pointed than the other. They are discharged at the 16–32 cell stage (Figure 7).

Life cycle

Eggs develop in 1–2 days and then hatch. L1 larvae molt to L2 larvae in 2–3 days and to the ensheathed filariform L3 larvae in 7–8 days. L3 larvae are resistant to desiccation. When ingested by humans with vegetables or drinking water the larvae develop in the intestinal mucosa, molting twice and developing into adult worms in approximately 4 weeks. Percutaneous infection may occur.

Transmission and epidemiology

Trichostrongylus infections have been reported from every continent. Infective larvae are relatively resistant to environmental pressures, and infections are thus prevalent even in relatively cold areas. In Iran, nine species have been recorded from humans; in central Iran, the incidence of *T. orientalis* and *T. colubriformis* has been recorded as 67 percent (Ghadirian and Arfaa 1975). In this region of the world, it is common for

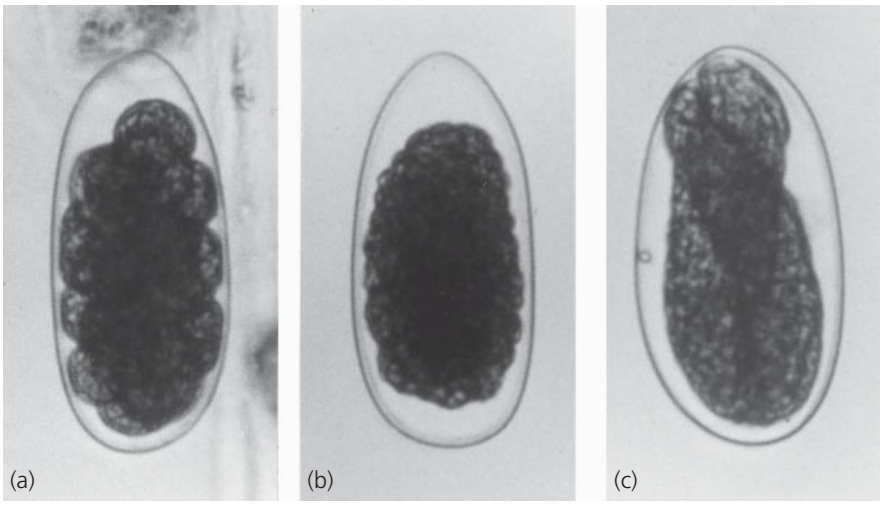

Figure 7 Trichostrongylus orientalis *eggs* **(a)** *as seen in fresh feces;* **(b)** *at the morula stage of embryonation;* **(c)** *with developed rhabdtiform larva (×600)*

women to mold animal dung into solid masses, to be dried and burnt as fuel. This practice may be important in the transmission of animal *Trichostrongylus* to humans. Human infections with *T. orientalis* are principally acquired by eating vegetables contaminated with night soil. In Japan, *T. orientalis* infection was previously common in cold areas, the prevalence in Aomori Prefecture in 1975 being approximately 19 percent, but the current figure is estimated to be very low (unpublished data).

Clinical manifestations and pathology

Trichostrongylids penetrate into the intestinal mucosa, producing redness, erosion, and local bleeding. Patients present with epigastric pain, diarrhea, anorexia, nausea, dizziness, and generalized fatigue or malaise (Otsuru and Ito 1972). If worm loads are light patients may be asymptomatic, but heavy worm loads are associated with the development of anemia, and the entry of worms into the biliary tract, provoking cholecystitis.

Diagnosis

Stool examinations are used to detect ova. Harada-Mori cultures are used to obtain L3 larvae for morphological differentiation. Several methods for detecting ova or larvae should be used, because females discharge only a small number of eggs daily.

Control

Pyrantel pamoate, bephenium hydroxynaphthoate, and 1-bromo-naphthol are effective. Ingestion of fresh vegetables or pickles contaminated with L3 larvae should be avoided. Caution must be used when handling animal dung to prevent infection with animal trichostrongylids.

ANISAKIS AND RELATED SPECIES

Introduction

Anisakids live in the stomach of marine mammals. *Anisakis simplex* was first discovered as a cause of larva migrans by van Thiel et al. (1960) who noted a nematode larva in the intestinal wall of a patient suffering from acute abdomimal pain after eating raw herrings. The larva was identified as *Eustoma rotundatum*, but the disease was later named 'anisakiasis' (van Thiel 1962). Prior to this discovery, cross-sections of a nematode-like parasite had frequently been recognized in Japanese patients suffering from acute terminal ileal enteritis, with prominent eosinophilic infiltration and severe allergic tissue reactions. These specimens were initially identified as *Ascaris* larvae. Later, *Anisakis* larvae were removed under gastric endoscopy (Namiki et al. 1970) and since then, many cases of gastric anisakiasis have been reported in Japan, linked to the habit of eating raw fish (sashimi or sushi). Anisakiasis has most frequently been found in Japan, followed by the Netherlands (where infections are acquired from ingesting raw herrings). The increasing popularity of 'sushi bars' has contributed to the spread of infections in the USA and Europe. Anisakid larvae parasitic to humans known to date are *Anisakis simplex*, *A. physeteris*, *Pseudoterranova decipiens*, *Contracaecum osculatum*, *Hysterothylacium aduncum*, and *Porrocaecum reticulatum*; *A. simplex*, and *P. decipiens* being the most important.

Classification and morphology

The genus *Anisakis* belongs to the order Ascaridida, family Heterocheilidae and subfamily Anisakinae. *P. decipiens* was initially called *Ascaris decipiens*, was

subsequently transferred to the genus *Porrocaecum*, *Terranova* or *Phocanema* and finally to the genus *Pseudoterranova* (Gibson 1983).

A. simplex L3 were initially called *Anisakis* type-I larva. The larvae have a dorsal lip and two subventral lips orally, with a boring tooth on the dorsal lip. The excretory pore opens at the base of the subventral lips. The esophagus is composed of two parts; the preventriculus and a relatively long ventriculus, with an oblique ventriculo-intestinal junction. The tail is short and rounded, with a mucron (Figure 8). Larvae measure 28.40 × 0.45 mm on average. *A. physeteris* was initially called *Anisakis* type-II larva. These measure 27.80 × 0.61 mm on average, have a short ventriculus, a horizontal ventriculo-intestinal junction, and a long tapering tail without a mucron (Figure 8).

L3 larvae of *P. decipiens* measure 32.6 × 0.8 mm on average and are yellowish-brown. The ventriculus partly overlaps the intestinal cecum posterior and there is a mucron at the tail end (Figure 8). In Japan, *P. decipiens* was previously called *Terranova* type A larva.

Anisakis species have a unique morphology in cross-sections; clear Y-shaped lateral cords (Figure 12), cuticular lateral alae absent, 60–90 muscle cells/quadrant, and 60–83 columnar intestinal cells. *P. decipiens* larvae have >100 intestinal cells and butterfly-like lateral cords (Oshima 1972).

Life cycle

Figure 10 summarizes the life cycles of *A. simplex* and *P. decipiens*. Adult worms live in the stomachs of marine mammals. Eggs (40 × 50 μm) are discharged with the feces, then the larvae molt once into the L2 stage, which hatch when ingested by euphausiid krill and develop into the L3 stage. When infected krill are eaten by squid or marine teleosts, e.g. salmon, cod, herring, and mackerel, the larvae encyst in the viscera or muscles (Figure 9), but do not develop further. When these paratenic hosts are eaten by marine mammals, the L3 larvae molt twice in the stomach and develop into adult worms. In Japan, *A. simplex* larvae have been found in 164 species of fish and one squid species, and adult worms have been found in 26 cetacean species and 12 species of pinnipeds. Marine mammals may be infected by ingesting crustacean intermediate hosts. Humans are not suitable hosts; L3 or L4 larvae are found, but never adult worms.

Isopods and mysids serve as intermediate hosts for *P. decipiens*. Cod, haddock, halibut, greenling, pollack, and other fish serve as paratenic hosts (Figure 10). L3 larvae have been found in nine species of fish in Japanese waters and 11 species in Californian waters (Ishikura et al. 1992). Seals, sea lions, and walruses act as definitive hosts (Figure 10). Adult worms have rarely been recovered from humans.

Transmission and epidemiology

Anisakiasis is linked to the ingestion of raw or undercooked marine fish or squid. Many fish are involved in *A. simplex* transmission in Japan (Figure 9) (Oshima and Kliks 1987; Kino et al. 1993). Pacific cod and halibut are important for transmission of *P. decipiens* in Japan. Other important sources of infection include rockfish, salmon, and red snapper in the USA (Kliks 1983; Oshima 1987) and herring in Europe (van Thiel 1976).

Human anisakiasis has been reported from many countries in Asia, Europe, North and South America, and New Zealand. In Japan, a total of 20 582 cases were reported between 1980 and 1993 (Ishikura et al. 1993), but only 660 cases were reported from other countries by the end of 1992. In Japan, 93 percent of cases involved the stomach and only 4.4 percent were intestinal. In other countries intestinal anisakiasis accounts for a much larger percentage of cases. The annual incidence in Japan is >2 000 cases. Changes in dietary habits may account for the escalation of anisakiasis in the USA, where >50 cases have been reported.

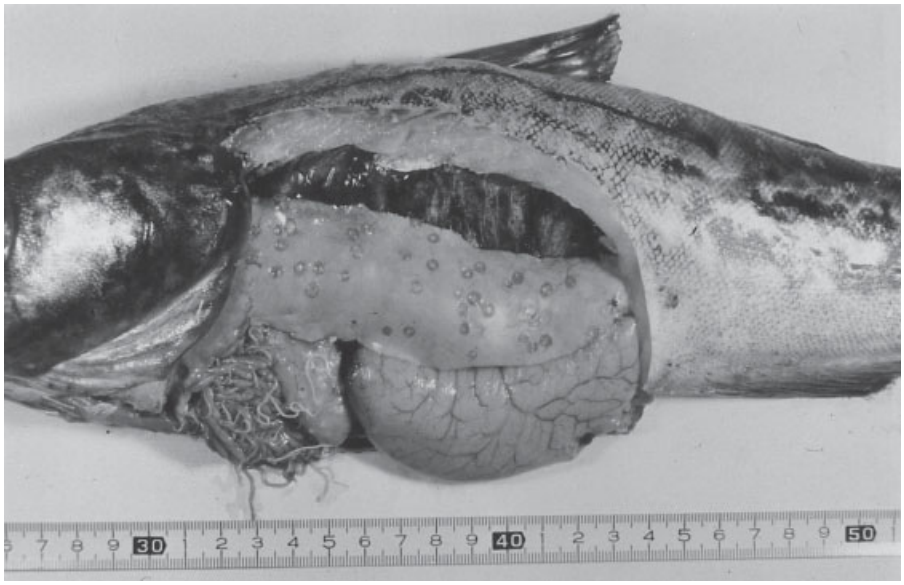

Figure 9 Anisakis simplex *third-stage larvae encapsulated in the liver of the pollack,* Theragra chalcogramma *(courtesy of Dr K. Ishida)*

Clinical manifestations

Clinical manifestations can be severe if a secondary infection induces a strong immediate hypersensitivity reaction around the site of worm penetration. Mild clinical symptoms result from local foreign body formation during a primary infection. The disease is also classified into gastric, intestinal, and extra-gastrointestinal (ectopic) anisakiasis. The last form is caused by larvae that penetrate into the abdominal or pleural cavity, entering abdominal or pleural organs or tissues (e.g. omentum, mesentery, peritoneum, liver, pancreas, ovary,

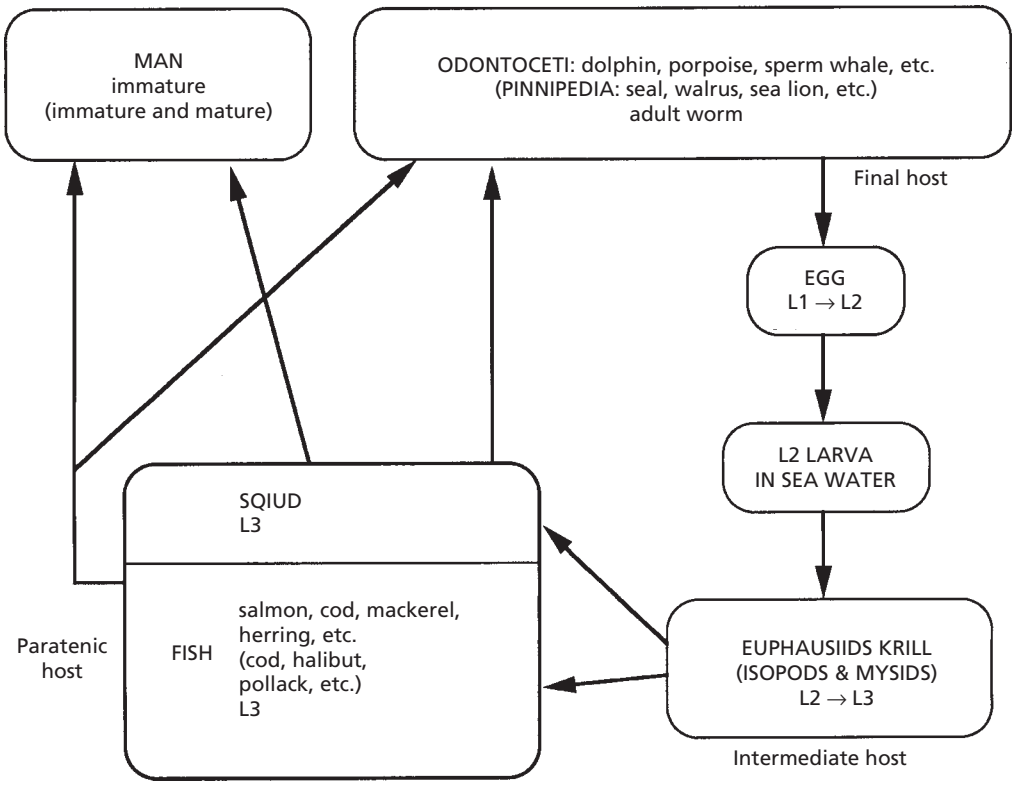

Figure 10 *Life-cycle of* Anisakis simplex *and* Pseudoterranova decipiens. *Names in brackets refer to host of* P. decipiens. *L1, L2, and L3: the first-, second- and third-stage larvae (adapted from Oshima 1987).*

oviduct, utero-cervix, lymph node, lung, and even in the subcutaneous tissue), and provoking inflammatory foci.

Acute gastric anisakiasis occurs approximately 6 h after the ingestion of raw seafood (Deardorff et al. 1991). Larvae normally parasitize the fundus of the stomach (rarely tongue, tonsil, uvula, and esophagus), especially the greater curvature (Figure 11). Symptoms are summarized in Table 4. Rarely, gastric anisakiasis may cause severe chest pain or angina-like pain (Sugano et al. 1993) that is often misdiagnosed as gastric ulcer, cancer, or polyp.

Acute gastric anisakiasis is rare in persons over 60 years of age and in patients who have undergone gastric surgery and this is a result of the low gastric acidity in these people (Muraoka et al. 1996).

Intestinal anisakiasis usually develops within 2 days after infection and occurs in any region between the duodenum and the rectum, most frequently in the ileal region (Matsui et al. 1985). Symptoms (Table 4) last for 1–5 days and then lead to ileus. Acute intestinal anisakiasis may cause ascites. The disease is frequently misdiagnosed. Patients usually have no pyrexia, but develop moderate leukocytosis and, in some cases, eosinophilia (4–41 percent) (Ohtaki and Ohtaki 1989; Ishikura 1990; Deardorff et al. 1991).

P. decipiens larvae are less invasive than *A. simplex*, are frequently expelled by vomiting, and rarely cause intestinal anisakiasis (Oshima 1987). Instead, they often provoke a tingling throat syndrome, associated with larval migration from the stomach to the mouth. In contrast, *A. simplex* larvae readily penetrate the gastrointestinal wall and invade the abdominal cavity, provoking peritonitis and intruding into various organs and tissues. Ectopic anisakiasis is usually mild and most cases are discovered accidentally during surgery (Ishikura et al. 1992).

Single worm infection is common, but multiple infections occur, for example approximately 50 *A. simplex* larvae were recovered from a Japanese patient (Takamuku et al. 1994).

A. simplex present in parasitized fish sometimes cause urticaria/angioedema, anaphylaxis, atopic dermatitis, arthralgias/arthritis associated with urticaria, and occupational asthma or conjunctivitis in persons handling fish (fishermen/fishmongers) or fish flour (Kasuya et al. 1990; de Corres et al. 1996; Anibarro and Seoane 1998; Armentia et al. 1998; Cuende et al. 1998). Patients presenting with dermatitis after handling fish should be suspected of having contracted protein-contact dermatitis caused by *A. simplex* (Anibarro et al. 1997). Patients with these allergic diseases show positive on skin prick test to *A. simplex* antigen, are positive for histamine release, and have both IgE antibody specific to the worm and a higher total IgE level (del Pozo et al. 1996; Cuende et al. 1998). *Anisakis* allergen is considered to be thermostable and thus, the ingestion of safely cooked but parasitized seafood causes an allergy. The high frequency of *Anisakis*-allergy and the severity of some cases are more important than gastrointestinal anisakiasis, and are becoming a public health problem especially in Spain. Asymptomatic gastro-intestinal anisakiasis sometimes accompanies allergic or anaphylactic reactions (Garcia-Labairu et al. 1999).

Hypersensitivity to *A. simplex* is associated with HLA class II DRB1*1502-DQB1*0601 haplotype, suggesting this haplotype is a susceptibility factor for hypersensitivity to *A. simplex* antigens (Sanches-Velasco et al. 2000).

Table 4 *Clinical symptoms of patients with gastric or intestinal anisakiasis*

Symptom/sign	No. of cases (%)	
	Gastric (363 cases)	Intestinal (124 cases)
Epigastric pain	228 (62.8)	16 (12.9)
Generalized abdominal pain	7 (1.9)	12 (9.7)
Lower abdominal pain	14 (3.9)	56 (45.2)
Epigastric distention	19 (5.2)	1 (0.8)
Abdominal bloating	3 (0.8)	13 (10.5)
Nausea	63 (17.4)	26 (21.0)
Vomiting	34 (9.4)	45 (36.3)
Heart burn	9 (2.5)	–
Anorexia	8 (2.2)	–
Tumor	8 (2.2)	8 (6.5)
General fatigue or malaise	7 (1.9)	1 (0.8)
Blood vomitus	7 (1.9)	–
Diarrhea	5 (1.4)	14 (11.3)
Other peritoneal irritation symptoms	1 (0.3)	18 (14.5)
Urticaria	4 (1.1)	–
Asymptomatic	21 (5.8)	6 (4.8)

Data from Totsuka (1974)

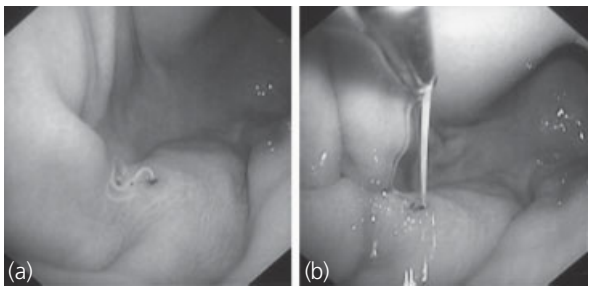

Figure 11 Anisakis *larvae just penetrating into the stomach mucosa* **(a)**. *The larva being removed with biopsy forceps of the endoscope* **(b)**. *(Courtesy of Dr I. Sato)*

Pathology

Initially, lesions are infiltrated mainly by neutrophils, with a few eosinophils and foreign body giant cells.

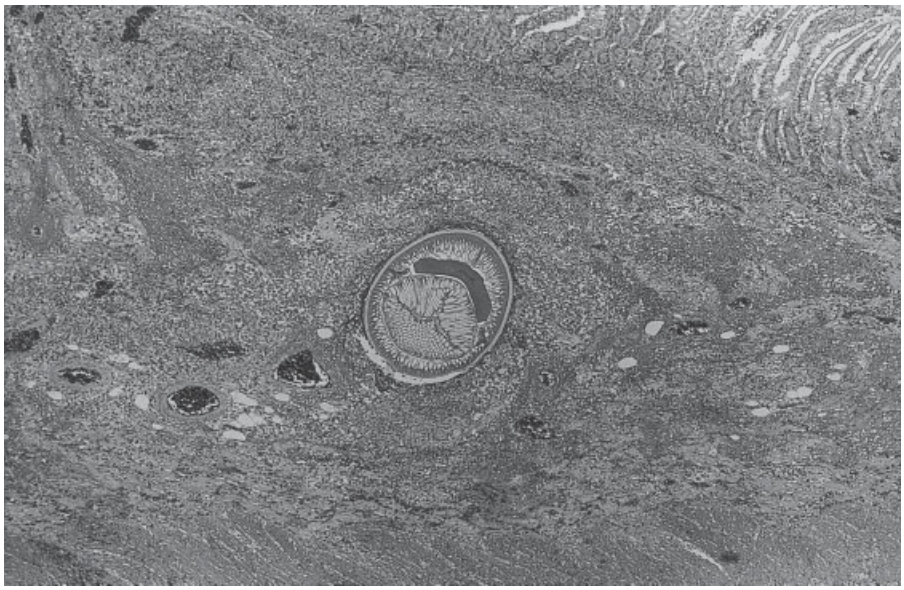

Figure 12 *Cross-section of an* Anisakis *larva invading the submucosa of the ileum. Note the characteristic 'Y-shaped' lateral cords and the rennette cell, and intense cellular infiltration around the larva (×47).*

There is little edema, fibrinous exudation, hemorrhage, or vascular damage. Within the first week there may be edematous thickening of the submucosa and infiltration by numerous eosinophils and other cells (Figure 12).
In chronic gastric and intestinal anisakiasis, necrotic and hemorrhagic abscesses with eosinophilic infiltration may be present. Eosinophilic infiltration becomes less extensive after 6 months and lymphocyte infiltration predominates. Degenerative worms may be surrounded by foreign body giant cells. In more advanced stages (6 months to 1 or more years) the abscess or granulomatous inflammation may be replaced by granulation tissue with some eosinophil infiltration. Fragments of the degenerated worm are usually, but not always, present.

Diagnosis

Clinical manifestations are not specific and therefore diagnosis is difficult, especially with intestinal or extra-gastrointestinal anisakiasis. When patients complain of abdominal pain, nausea, and vomiting, their dietary history immediately prior to the onset of the symptoms should be determined. If raw seafood has been eaten, diagnostic measures must be performed.

ENDOSCOPY

Endoscopy is useful for gastric anisakiasis and sometimes for duodenal anisakiasis (Kliks 1986). The site of larval penetration is edematous, with various degrees of hyperemia, erosion, and bleeding. The penetrating *Anisakis* larva can be easily removed endoscopically with biopsy forceps (Figure 11).

RADIOLOGY

Radiology is effective for diagnosing intestinal anisakiasis. Double-contrast, barium-filled roentgenographic images reveal coiled or thread-like filling defects. Edematous, thickened, narrowed, and obstructed areas in the gastrointestinal walls are present (Sugimachi et al. 1985; Matsui et al. 1985). *Anisakis* infection may also cause a vanishing tumor of the stomach.

Sonographic examination is useful for the diagnosis of intestinal anisakiasis when the combined findings of ascitic fluid, dilation of the small intestine, and localized edema of Kerckring's fold is observed in the patients with acute abdomen after recent ingestion of seafood (Ido et al. 1998).

IMMUNODIAGNOSIS

Although several serological tests are used, their application has limitations because of cross-reactions with other nematodes and because low levels of specific antibody may be present in acute anisakiasis. Nevertheless, immunodiagnosis is essential for chronic infections, intestinal, and extra-gastrointestinal anisakiasis. Takahashi et al. (1986) established two monoclonal antibodies, one of which (An2) recognized a specific epitope in the intestine, muscle cells, and E-S products of the larvae. A micro-ELISA assay using this antibody has been developed (Yagihashi et al. 1990). Antilarval *A. simplex*-specific IgG, IgA, and IgM antibodies are detectable 4–5 weeks after the onset of disease; specific IgE antibody can be detected as early as 1–7 days. An immunoblot assay, using E-S antigens of *A. simplex* larvae and detecting IgA or IgE antibodies specific for E-S antigens of the larvae, is also useful (Akao et al. 1990).

IgE immunoblotting with *A. simplex* antigen, positive skin prick test to *A. simplex* but not to fish, and antigen-capture ELISA using O-deglycosylated antigen bound by the monoclonal antibody UA3 are useful approaches to *Anisakis*-allergy diagnosis (del Pozo et al. 1996; Garcia et al. 1997; Lorenzo et al. 2000). More recently, determination of specific IgE directed to *A. simplex* major allergen (24 kDa and named Ani s 1) by immunoblotting has been shown to be a useful tool for the diagnosis of hypersensitivity and intestinal anisakiasis, whereas measurement of specific IgG to Ani s 1 is only valid for *A. simplex* allergy (Caballero and Moneo 2002).

Control

Gastric endoscopy is effective for locating and removing penetrating larvae. If diagnosis is confirmed and there is no ileus, surgical treatment is not necessary. Instead, supportive treatment is recommended until the larvae die and are absorbed. In experimental animals this occurs within 3 weeks (Jones et al. 1990).

Thorough cooking and adequate freezing of seafood are easy and practical preventive measures. In the Netherlands, legislation (The Green Herring Law) requires fresh herring to be frozen to at least −20°C for 24 h before release to the public. Fish should be cooked so that the internal temperature reaches 60°C or higher for 10 min. Seafood should be frozen at −20°C for 3–5 days (Sakanari and McKerrow 1989; Deardorff et al. 1991). At room temperature, *Anisakis* larvae can survive for many days in vinegar, and for 1 day in soy sauce or Worcester sauce. The larvae may be harmed, but not killed, by gastric fluid. Microwave processing of seafood, for example, arrowtooth flounder fillet, to kill *A. simplex* larvae is effective only when the internal temperature of the fillet reaches higher than 77°C (Adams et al. 1999).

GNATHOSTOMA SPECIES

Owen (1836) collected worms from a stomach wall tumor of a tiger in the London Zoological Gardens and named them *G. spinigerum*. The genus now contains 12 distinct species, four of which (*G. spinigerum*, *G. hispidum*, *G. doloresi*, and *G.nipponicum*) are zoonotic in South East Asia and the Far East.

The number of patients in Mexico has been increasing since the first recorded case in 1970, and the estimated number of patients was more than 1 380 even between 1980 and 1996 (Ogata et al. 1998). Although the causative agent of the human infections in Mexico and Ecuador was identified as *Gnathostoma binucleatum* (Almeyda-Artigas 1991), the validity of *G. binucleatum* and its involvement in human gnathostomiasis was questioned (Akahane et al. 1994; Diaz-Camacho et al. 1998; Ogata et al. 1998). A recent comparative study on ITS-2 rDNA sequences of Mexican *Gnathostoma* spp. indicates that *G. binucleatum* is a valid species and incriminated as an etiologic agent of human gnathostomiasis in Mexico and Ecuador (Almeyda-Artigas et al. 2000). In Sinaloa, Mexico, *Gnathostoma* advanced third-stage larvae have been recovered from ichthyophagous birds, e.g. *Egretta alba*, and several fishes, e.g. blue sea catfish (*Arius guatemalensis*), Pacific fat sleeper (*Dormitator latifrons*), fat sleeper (*Gobiomorus* sp.), Nile tilapia (*Oreochromis* sp.), Sinaloan cichlid or green guapote (*Cichlasoma beani*), and spotted sleeper (*Eleotris picta*) (Diaz-Camacho et al. 2002). Moreover, the first human infection of *Gnathostoma malaysiae* was recently found in two Japanese travelers returning from Myanmar (Nomura et al. 2000). These patients ate raw freshwater shrimp in Myanmar and then showed a creeping eruption and Quincke's edema.

G. spinigerum is the most important species in Asia, causing cutaneous, cerebrospinal, and ocular lesions. *G. hispidum* was first found to cause human cutaneous gnathostomiasis in Japan (Tsushima et al. 1980), and many cases have subsequently been reported. *G. doloresi*, and *G. nipponicum* have also been shown to provoke creeping eruption in humans in Japan (Ogata et al. 1988; Ando et al. 1988). *G. hispidum*, *G. doloresi*, and *G. nipponicum* usually provoke creeping eruption and rarely affect deeper tissues. They differ from *G. spinigerum* in not causing long-term (>10 years) recurrent cutaneous lesions and they have not been recognized outside Japan.

GNATHOSTOMA SPINIGERUM OWEN, 1836

Introduction

Gnathostoma spinigerum was first discovered in 1889 in Thailand and named *Cheiracanthus siamensis* n. sp., later identified as *G. spinigerum*. Subsequently, many human cases have been reported from various South East Asian countries, Japan, and China. In Thailand, eosinophilic-encephalitis, myelitis, radiculitis, and subarachnoid hemorrhage caused by *G. spinigerum* are often confused with eosinophilic meningoencephalitis caused by *Angiostrongylus cantonensis*; differential diagnosis is therefore important in this country.

Classification and morphology

This genus belongs to the order Spirurida, superfamily Gnathostomatoidea. The adult males and females are 12–30 and 15–33 mm long, respectively. The head-bulb bears between eight and 11 rows of cuticular hooklets. The anterior body has toothed spines. The posterior body is naked apart from the presence of minute terminal spines. Males have four pairs of large papillae in the

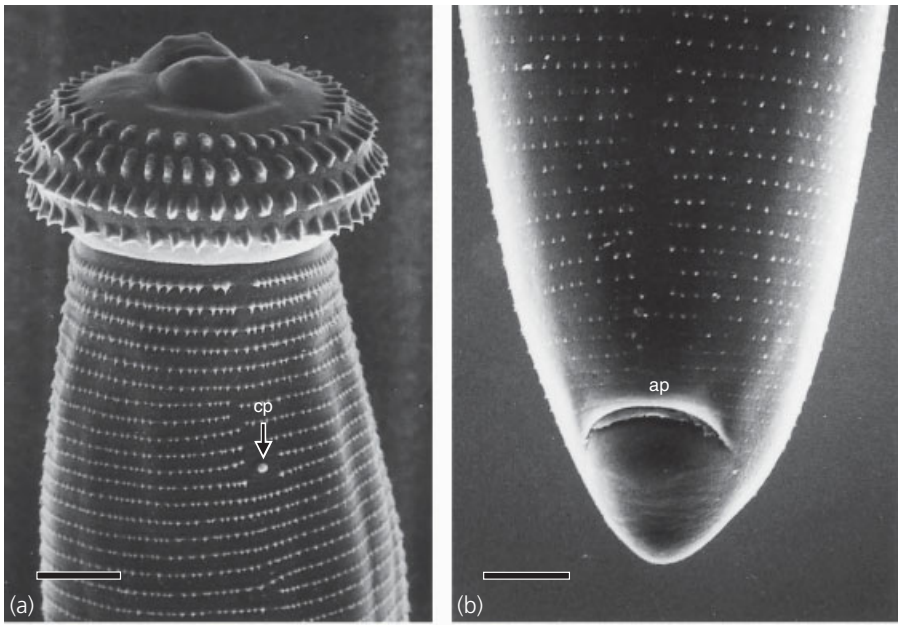

Figure 13 *Advanced third-stage larva of* Gnathostoma spinigerum. **(a)** *Anterior end. cp, cervical papilla. Bar, 30 μm;* **(b)** *ventral surface of the terminal end. ap, Anal pore. Bar, 20 μm (courtesy of Dr M. Koga)*

caudal alae and four pairs of small ventral papillae around the cloaca. Spicules are unequal in length, one being between three and four times longer than the other. The vulva is situated just behind the middle of the body. Eggs (measuring 69.3 × 38.5 μm on average) are oval, brownish, and unsegmented with a transparent knob-like thickening at one pole.

Advanced L3 larvae are 3–4 mm long (Figure 13 and Table 5). The body is entirely covered with cuticular spines. The morphology of the intestinal epithelial cells of the larvae is shown in Table 6.

Life cycle

G. spinigerum adult worms occur naturally in the cat, dog, and many other carnivores. In northern Thailand, 4.1 percent of 2 940 dogs examined had adult worms in stomach nodules (Maleewong et al. 1992). Eggs laid in these nodules pass into the gastric lumen through a small aperture and are discharged into the feces. L1 larvae develop in the eggs and molt to the L2 stage (Figure 14) after which the eggs hatch. L2 larvae are ingested by an aquatic crustacean (*Cyclops*), after which they develop in the hemocoele and molt into the early L3 stage in 6–10 days.

When early L3 larvae are ingested by freshwater fish, they penetrate into the gut, reaching the muscle and developing into the advanced L3 larvae, measuring 2.8–5.2 × 0.3–0.8 mm. These lie coiled and encysted by connective tissues (Daengsvang 1982). If hosts with L3 larvae are eaten by paratenic hosts (reptiles, birds, or mammals), the larvae encyst again. Advanced L3 larvae have been found in 44 species of vertebrates in Thailand and in 36 species of animals in Japan. Rusnak and Lucey (1993) have listed the many species that can serve as natural and experimental hosts.

When advanced L3 larvae are ingested by a final host they excyst in the stomach, then penetrate the gastric wall to the peritoneal cavity to reach the liver. Subsequently, they migrate through the host and 4 weeks later, they return to the stomach, penetrating the gastric wall from the outside to form a tumor that connects with the stomach lumen through a small aperture. The adult worm develops within 4.5–6 months after infection. Although the adult stage can develop in humans, the worms cannot return to the stomach (Miyazaki 1991).

Transmission and epidemiology

Infections are normally acquired by ingestion of second intermediate or paratenic hosts or, possibly, by drinking water containing infected *Cyclops* or free L3 larvae. Although the most important source of infections is snake-headed fish in both Thailand and Japan, many other species of fish, amphibia, reptiles, birds, and mammals are possible sources. People from Thailand often become infected by eating raw or fermented fish flesh, or raw or undercooked chicken flesh. Freshwater fish and chickens are major sources of human infections in Japan. The incidence of infection in snake-headed fish varies, but overall ranges from 44 to 99 percent (Daengsvang 1982). In Thailand, the incidence in freshwater eel has been reported to reach 80–100 percent, thus both the eel and snake-headed fish are epidemiologically important. Three possible human cases of prenatal infections have been documented (Rusnak and Lucey 1993).

Table 5 *Differential diagnosis of advanced third-stage larvae of four species of* Gnathostoma

Species	No. of hooklets on head-bulb				Remarks	Reference
	1st row	2nd row	3rd row	4th row		
G. spinigerum	43.2	44.8	46.7	52.3	The number of hooklets in each row is more than 40, increasing posteriorly	Miyazaki (1960)
G. hispidum	38.3	40.5	41.8	46.0	The number of hooklets gradually increases posteriorly. The first row of hooklets are smaller than the others	Akahane et al. (1982)
G. doloresi	38.3	37.9	35.6	35.7	The number of hooklets in each row is fewer than 40, decreasing posteriorly. The hooklets in the first row are especially small	Mako and Akahane (1985)
G. nipponicum	37.0	37.1	41.0	–	Lack the fourth row of hooklets	Ando et al. (1988)

Table 6 *Differential diagnosis in cross-section of the abdominal region of advanced third-stage larvae of four species of* Gnathostoma

Species	No. of muscle cells/ quadrant	Number	Intestinal cell shape	No. of nuclei
G. spinigerum	10–15	21–29	Columnar	0–7 (mostly 3–7)
G. hispidum	11–15	19–31	Spherical	0–2 (mostly 1)
G. doloresi	11–15	18–28	Spherical	0–3 (mostly 2)
G. nipponicum	10–14	10–14	Columnar	0–4 (1 in 50% of cells)

After Ando et al. (1991).

Advanced L3 larvae can penetrate the intact skin of mice, rats, and cats, with complete penetration occurring within 30 min. Human infections may also be acquired by this route (Rusnak and Lucey 1993).

Human gnathostomiasis has been recorded from 19 countries, predominantly in Asia, especially Thailand and Japan. In Thailand, infections mainly occur in the rainy season (Punyagupta et al. 1990) and are most prevalent in females, aged 20–25 years, whereas in Japan, they are most prevalent in males in their twenties (Daengsvang 1982). The youngest recorded case in Japan was an infant less than 2 years old.

Clinical manifestations and pathology

Gnathostomiasis spinigera has cutaneous and visceral forms and the latter is divided into pulmonary, gastrointestinal, urogenital, ocular, otorhinolaryngeal, and cerebral forms (Rusnak and Lucey 1993). Patients develop various prodromes, e.g. general malaise, anorexia, urticaria, vomiting, epigastric pain, diarrhea, and fever in about the first 5 days after infection, i.e. when L3 larvae excyst, penetrate into the peritoneal cavity, and migrate through the liver. Right upper quadrant pain may be experienced. The larvae then migrate to various parts of the body, most frequently to muscle and subcutaneous tissues. A specific cutaneous symptom, i.e. migrating intermittent swelling, usually develops within 1 month after infection, but may sometimes occur 1 or 2 years later. During this process, tissues or organs are mechanically injured by the migrating worms and probably also by the toxins they release (Miyazaki 1960). The lesions thus become enlarged, with allergic inflammation around infected foci. Worms in human tissues are not encysted.

In cutaneous gnathostomiasis, migrating swelling frequently appears first in the abdominal area, after which the lesion migrates at random. Worms move at about 1 cm/h in human skin. Swellings are rather hard, variable in size, and mostly erythematous. Skin lesions are normally painless apart from light or moderate itch. Swellings last 1–2 weeks and then disappear, another swelling appearing elsewhere. Migrating swellings may recur intermittently for up to 10–12 years. Worms migrating near the body surface may cause creeping eruption, cutaneous abscesses, or cutaneous nodules, from which the worms can often be resected. Inflammatory foci with profound eosinophilic infiltration are commonly seen in the skin lesions.

Migrating worms in deeper tissues produce visceral gnathostomiasis and serious symptoms may develop, depending on the organs or tissues affected (Rusnak and Lucey 1993). An acute or chronic inflammatory reaction occurs around invading worms and local hemorrhage, necrosis, edema, fibrosis, and tumor formation may occur. When the lungs are affected,

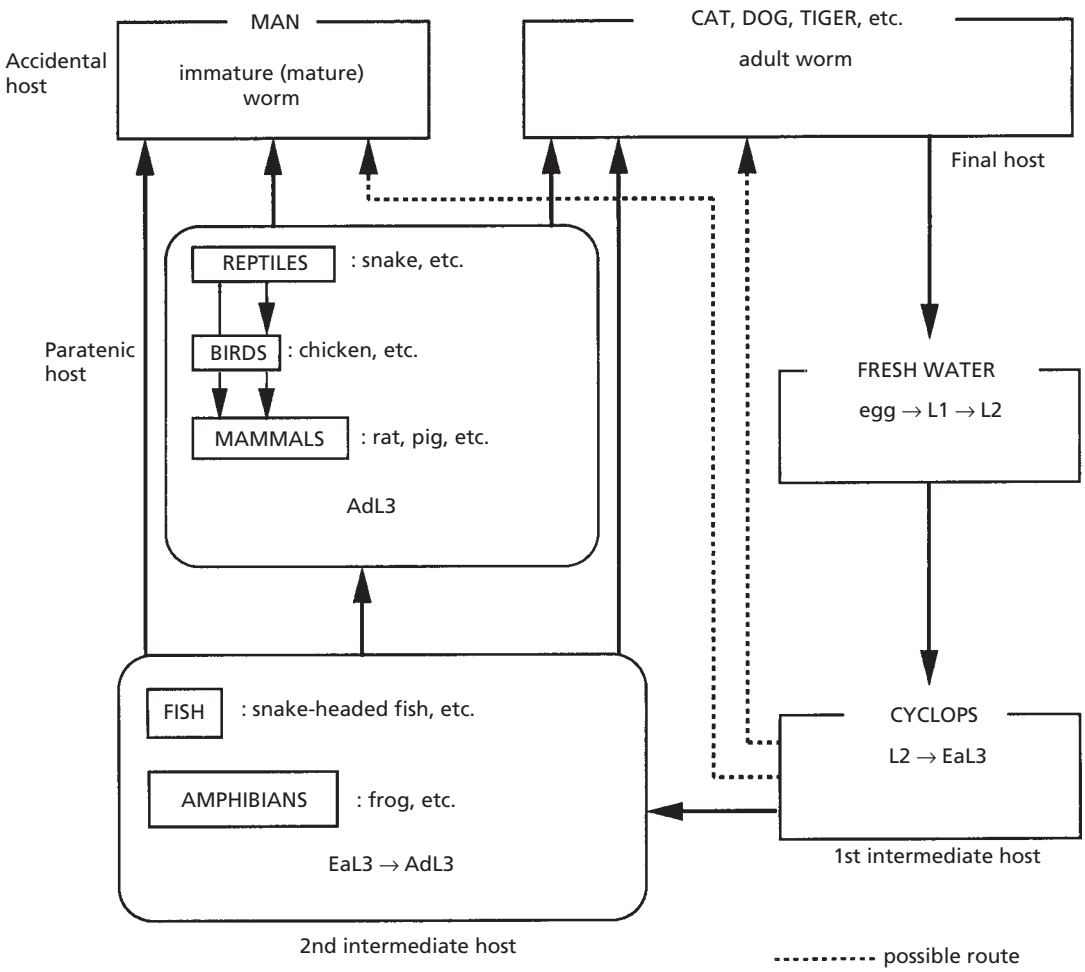

Figure 14 *Life-cycle of* Gnathostoma spinigerum. *L1 and L2, the first- and second-stage larvae; EaL3, early third-stage larva; AdL3, advanced third-stage larva.*

respiratory symptoms occur. Involvement of the gastrointestinal tract is rare and usually asymptomatic, only being found incidentally at surgery. Urogenital involvement is also rare. Ocular involvement presents as pain and visual impairment, with a variety of signs (Teekhasaenee et al. 1986). Iris holes, uveitis, and subretinal hemorrhage with subretinal tract are characteristic features of intraocular gnathostomiasis (Biswas et al. 1994). Involvement of the ear, nose, and throat is always preceded by facial swellings; worms may extrude from tissues and there may be dyspnea and difficulty in swallowing. The prognosis of gnathostomiasis with CNS involvement is poor and the infection is sometimes fatal (Punyagupta et al. 1990). A common clinical symptom in this form is radiculomyelitis, typically characterized by excruciating radicular pain associated with a burning sensation, which may last for 1–5 days as the worms migrate from the nerve root. When a cranial nerve or a cervical nerve is affected, the patient develops severe headache, convulsion, vomiting, paraesthesia, and unconsciousness, followed by paralysis or weakness of the extremities. In Thailand, differential diagnosis between cerebral angiostrongyliasis and gnathostomiasis is required, because both involve marked eosinophilia in the spinal fluid (Table 2).

Initially, patients show peripheral leukocytosis and 5–96 percent eosinophilia, but both these signs later gradually decrease. Patients with ocular gnathostomiasis show normal hematology. Cerebral gnathostomiasis usually shows xanthochromic cerebrospinal fluid with numerous leukocytes, especially lymphocytes and eosinophils (8–98 percent), and some erythrocytes. Protein in the spinal fluid is unchanged or slightly elevated, whereas glucose is normal (Table 2). Computed tomography of the head is useful for diagnosis of intracranial hemorrhage or obstructive hydrocephalus. Death is usually due to direct involvement of the brain stem and massive hemorrhage in this area; mortality ranges from 8 to 25 percent (Rusnak and Lucey 1993).

Diagnosis

If biopsy specimens or sections containing worms are available, diagnosis can be made morphologically

(Tables 5 and 6). Recovery of worms is not always possible and therefore serological tests have also been employed. An ELISA test using crude extract of advanced L3 larvae or their E-S products is used for detecting antigen specific IgE (Soesatyo et al. 1987) or IgG antibody (Tuntipopipat et al. 1989) in sera or spinal fluid. A 24-kDa glycoprotein antigen from advanced L3 larvae is specific to *G. spinigerum* and is thus useful for immunodiagnosis (Nopparatana et al. 1991; Tapchaisri et al. 1991). E-S antigens from advanced L3 larvae give a better diagnostic result than crude somatic extracts. Furthermore, an ELISA assay with low molecular weight E-S or somatic antigens (less than 29 kDa), purified by a simple two-step fractionation process, is sensitive and specific (Tuntipopipat et al. 1993). Detection of circulating antigens seems to be unreliable (Tuntipopipat et al. 1989).

Control

Until recently, there were no effective routine therapeutic measures other than surgical removal of worms, which is not always feasible; supportive, symptomatic, and anti-inflammatory treatments were recommended. Recently, however, it has been shown that cutaneous gnathostomiasis can be treated successfully with a single 3-week course of albendazole (400 mg) either once or twice daily (Kraivichian et al. 1992; Crowley and Kim 1995). Ivermectin is also effective and more convenient in a single-dose treatment (Nontasut et al. 2000). Preventive measures include avoidance of raw or inadequately cooked hosts that may contain L3 larvae and avoidance of drinking water that may contain infected *Cyclops*. L3 larvae are killed by boiling for 5 min or freezing at −20°C for 3–5 days (Schantz 1989; Rusnak and Lucey 1993). Use of gloves or frequent washing of hands while handling food is recommended to prevent possible larval penetration of the skin. Relatively recent increases in world travel and importation of food mean that greater awareness of gnathostomiasis spinigera is required, even in the USA and European countries.

GNATHOSTOMA HISPIDUM FEDTSCHENKO, 1872

Introduction

Gnathostoma hispidum was discovered in 1872 in wild pigs in Turkestan and in domestic pigs in Hungary. Since then it has been found in pigs in Germany and many Asian countries (Daengsvang 1982). Two doubtful human cases were described in 1924 and 1949, and four cases of creeping disease were more recently found in Japan (Tsushima et al. 1980). Subsequently, a further 79 cases of cutaneous gnathostomiasis due to *G. hispidum* have been recognized in Japan (Ando 1992).

Morphology

Adult worms live in the stomach wall, singly or in groups of a few worms, without producing a tumor. Males are 20 mm long and females are 25 mm long. Fresh specimens are red. The head-bulb bears between nine and 12 rows of cephalic hooklets and the entire body surface is covered with cuticular spines. Eight pairs of papillae are located caudally in the male worm, whereas the female has one pair of papillae. Eggs resemble those of *G. spinigerum*, but are slightly larger (72 × 40 μm). Advanced L3 larvae from humans measure approximately 900 μm (Tables 5 and 6).

Life cycle

Eggs shed in swine feces release L2 larvae in approximately 2 weeks. If ingested by *Cyclops* they molt into early L3 larvae in approximately 8 days. These develop into advanced L3 larvae in second intermediate or paratenic hosts (e.g. fish, amphibians, and rodents) and become encysted in their muscles. Prevalence in loaches from the Beijing and Nanjing areas has been estimated at 12 and 6 percent, respectively (Akahane et al. 1982). In China, advanced L3 larvae have been found in 14 species of freshwater fish, frogs, snakes, chickens, and rats, the incidence in snakes being 100 percent (Chen and Lin 1991). The prepatent period in pigs varies from 3 to 6 months. Unlike *G. spinigerum*, *G. hispidum* cannot mature in humans. Experimentally, cats and rats can be infected by skin penetration of advanced L3 larvae.

Transmission and epidemiology

Humans acquire infections by eating raw loaches containing early L3 larvae or by consuming various vertebrates containing advanced L3 larvae. All human infections in Japan have come from loaches imported from China, Korea, and Taiwan.

Clinical manifestations and pathology

Clinical symptoms develop 3 weeks to 3 months after infection. Initially, patients complain of anorexia, diarrhea, and abdominal pain. All cases in Japan showed creeping eruption or mobile speckled erythema and a few also showed migratory intermittent swellings. Creeping eruption with erythema and itch normally occurs on the trunk or extremities. Morita et al. (1984) classified the disease into five types: (1) skin creeping eruption, on trunk and extremities; (2) migrating tracks on the liver; (3) migrating speckled erythema; (4) cerebrospinal form; and (5) Löffler's syndrome revealed by transient pulmonary infiltration on X-ray. Blood leukocytosis and eosinophilia (up to 84 percent) commonly

occur, peaking 1–2 months after infection. Serum IgE levels are highly elevated. Clinical manifestations normally disappear within 3 months and never recur.

Monkeys experimentally infected with larvae from loaches yielded 64 percent encysted advanced L3 larvae after 466 days (Koga et al. 1988). This suggests that encysted larvae may survive in human musculature for long periods.

Diagnosis

Morphological diagnosis (Table 6) is possible using resected whole worm specimens or sections. Patients with creeping eruption and peripheral eosinophilia, and a history of eating raw loaches from endemic areas, should be examined for antignathostome antibody. Crude *G. spinigerum* antigens are commonly used in Japan, because *G. hispidum* antigens are unavailable.

Control

No effective drugs are available. Ingestion of raw loaches from endemic areas or flesh from chickens fed with loaches should be avoided.

GNATHOSTOMA DOLORESI TUBANGUI, 1925

Introduction

Gnathostoma doloresi was first discovered by Tubangui (1925) in the stomach wall of a pig in the Philippines. Later, it was also noted in pigs in India by Maplestone (1930) and it has subsequently been recovered from domestic pigs and wild boars in many Asian countries. The first human infections (with creeping eruption) were found by Ogata et al. (1988) in Japan. All eight patients had a history of eating local freshwater fish. Larvae were found in the skin of three out of eight patients. As of 2001, 58 human cases have been noted from Japan.

Morphology

Adult worms occur singly or in groups of two to three worms in the gastric walls of domestic pigs or wild boar, inserting the anterior body into the thickened gastric wall. Males are 20 mm long and females are 34 mm long. The posterior half of the body is thicker than the rest. Worms are covered with cuticular spines, except for a small area at the tail end of the male. Males have eight pairs of caudal papillae. Eggs are 61.3 × 30.9 μm on average, with transparent knob-like bulges at both ends.

Advanced L3 larvae are approximately 3 mm long. The head-bulb has four rows of cephalic hooklets, those in the first row being extremely small. The average number in each row is <40 (Table 5). The morphological characteristics of cross-sections are presented in Table 6.

Life cycle

The recent incidence of infection in wild boars examined at two locations in Miyazaki Prefecture, Japan was 95 and 100 percent with an average of 20 and 57 worms per boar, respectively (Ishiwata et al. 1998); in Thailand the incidence in pigs was 2.1–8.7 percent (Daengsvang 1982).

Eggs shed into the feces develop to the L2 stage. These develop in *Cyclops* to the early L3 stage. If *Cyclops* are eaten by fish or amphibians, advanced L3 larvae develop. Snakes that feed on these second intermediate hosts can act as paratenic hosts. The prevalence in the poisonous snake *Agkistrodon halys* has been recorded as 100 percent (Imai et al. 1988). A pig infected with advanced L3 larvae from *A. halys* shed eggs 58 days after infection (Imai et al. 1989).

Transmission and epidemiology

In Japan, freshwater fish are probably the major source of human infections, although several infections occurred by ingesting of the flesh of *A. halys*. *G. doloresi* advanced L3 have been found in a freshwater fish, *Lepomis macrochirus* (common name: blue-gill), which had been ingested by some past patients (Nawa et al. 1993).

Clinical manifestations and pathology

Before cutaneous symptoms develop, patients may experience prodromes (such as fever, 'cold-like' symptoms, vomiting, abdominal pain, weakness, and malaise). Infections normally provoke creeping eruption with local pain and itch on the skin, particularly the trunk, and migratory swellings sometimes develop (Quincke's edema). Creeping eruption leaves pigmentation in the skin. Histopathologically, there is prominent eosinophil infiltration. Total serum IgE may be elevated and patients may show peripheral eosinophilia (6–67 percent).

Miyamoto et al. (1994) reported a case of pulmonary involvement in a patient with right chest pain and high fever. Clinical examination showed eosinophilia (18 percent), elevated IgE, a nodular lesion on r-S4 as revealed by plain X-ray and computed tomography, and anti-*G. doloresi* antibody. No cutaneous lesions developed. A case with an ileus due to an eosinophilic nodular lesion around migrating larvae in the colonic subserosa (Seguchi et al. 1995) and an intraocular case (uveitis) (Sasano et al. 1994) have also been reported. *G. doloresi* larvae can migrate to almost any location in the human body, e.g. the liver and CNS, and give rise to a variety of clinical manifestations.

Diagnosis

Various serological tests employ *G. doloresi* crude extracts as an antigen. If excised skin containing migrating worms is available, the species may be identified by the morphology of whole worms or cross-sections (Tables 5 and 6).

Control

No effective drugs are available. The best treatment is to excise worms from the skin lesions, if this is possible. No fatal cases have been reported. It is advisable to avoid eating raw, freshwater fish from local rivers in endemic areas.

GNATHOSTOMA NIPPONICUM YAMAGUTI, 1941

Introduction

This species was first found in the esophagus of weasels in Japan, and was mistakenly identified as *G. spinigerum*. It was subsequently renamed *G. nipponicum* by Yamaguti (1941) and has since been found in weasels in various regions of Japan (incidence of 40 percent). The species may also exist in China.

Ando et al. (1988) reported patients in Japan with creeping eruption after eating raw loaches; a *G. nipponicum* larva was found in a skin biopsy specimen. Since then, more than 15 patients with similar gnathostomiasis have been noted.

Morphology

Adult worms live singly or in groups in a hard tumor of the esophageal wall of the weasel, located 2–3 cm from the stomach. The anterior body is embedded and the posterior lies free in the lumen. Adult males are 20–23 mm long and females are 29–34 mm long. The anterior body is covered with cuticular spines, as in *G. spinigerum*, but there are no spines caudally in the female. There are also differences in the shape of the spines of *G. nipponicum* and *G. spinigerum* (Miyazaki 1960, 1991). The caudal alae of the male have small cuticular spines and eight pairs of papillae. Eggs measure 72.3 × 42.1 μm on average, with a transparent knob-like bulge at one end.

Advanced L3 larvae are found encysted in the muscles of the second intermediate or paratenic hosts. They have only three rows of hooklets on the head-bulb (Table 5). Morphological features of the cross-sections of the larvae are presented in Table 6.

Life cycle

L2 larvae released from fully developed eggs are eaten by *Cyclops* and molt to early L3 larvae. When cyclops are eaten by loaches, the larvae develop to the advanced L3 stage and encyst. Several species of freshwater fish, amphibians, and mammals can act as second intermediate hosts and several species of reptiles, birds, and mammals act as paratenic hosts (Ando et al. 1992). Weasels experimentally infected with advanced L3 larvae shed eggs 3 months after infection. Ferret and mink also serve as experimental hosts.

Transmission and epidemiology

Humans acquire infections by ingesting raw or inadequately cooked loaches or catfish. Recently, a human infection occurred through ingestion of raw, largemouth, black bass (*Micropterus salmoides*) in Akita, Japan (Ishida et al. 2003).

Clinical manifestations and pathology

All 15 cases studied to date developed creeping eruption on the abdomen, waist, and hip areas. The patients had all ingested loaches or various freshwater fish 3 to 4 weeks before the onset of symptoms. Some had peripheral eosinophilia (maximum 29 percent); leukocytosis was not always seen.

Diagnosis

Excised worms or resected skin specimens can be used for morphological identification (Tables 5 and 6).
Some patients show a positive serological reactions, but data are still scanty.

Control

Excision of worms is the best therapeutic measure if feasible. Mebendazole was effective for stopping the creeping eruption (Taniguchi et al. 1991). Eating raw freshwater fish must be avoided in endemic areas.

SPIRUROID TYPE X LARVA

Since 1991, many human cases have been reported from Japan of a creeping disease (most often with blister formations) caused by the type X larva of suborder Spirurina. This larva was first described by Hasegawa (1978) and has subsequently been recovered from human skin, the intestinal wall (especially ileum), and the anterior chamber of the eye. Sometimes, the larvae show intrahepatic erratic parasitism and provoke intestinal perforation. The adult stage has not been identified. Kagei (1991) suggested that the larvae of Spiruroid nematodes

other than the Spiruroid type X larva might cause cutaneous or visceral larva migrans.

Spiruroid type X larvae measure 6.7–8.0 × 0.08–0.10 mm, with two tubercles at the tail and two pseudolabia at the head. Larvae detected in sections of resected skin are 80–100 μm in diameter with characteristic cuticular annulations and intracuticular striae. The muscle layer is polymyarian-coelomyarian. Lateral cords are large and Y-shaped. The esophagus has muscular and glandular parts, the latter filled with minute granules that resemble secretory granules or vacuoles. The intestine has between five and six columnar intestinal cells.

These larvae have been found in marine fish which are therefore possible sources of human infections. Some species of squid also harbor type X larvae. Firefly squid are probably the most important source of human infections, because they are the type most frequently eaten raw in Japan. Spiruroid type X infections in humans occur predominantly, especially during March to June, and as of 2001, there are more than 70 cases in Japan.

The disease is classified into ocular, cutaneous, and intestinal (ileus) forms. Cutaneous symptoms develop as early as 2–9 days after eating raw squid (Shinozaki et al. 1993). There is usually only a transient, linear, or meandering erythema, without significant leukocytosis or eosinophilia. Some cases showed a significant rise of serum total IgE levels. Testing with immunofluorescence assay (IFA) or ELISA is recommended for the immunodiagnosis of the disease.

Effective therapeutic measures are unavailable. Most patients with ileus undergo surgical resection of the intestinal lesions and confirmed diagnosis is then made. It is recommended that firefly squid are frozen at −32°C for 30 min or more (in practice at −40°C for more than 40 min) to prevent infection (Akao et al. 1995).

Dracunculiasis

RALPH MULLER

Morphology	1	Diagnosis	3
Life cycle	1	Treatment	3
Transmission and epidemiology	1	The eradication campaign	3
Location in host	2	Zoonotic aspects	4
Clinical manifestations and pathology	2	References	4

Dracunculiasis is an ancient disease quoted by many classical authors and possibly mentioned in the Old Testament. For the last few years, there has been a world eradication campaign and this chapter has been written in the light of this campaign (Chippaux 1994; Cairncross et al. 2002). It is hoped that it will be superfluous in the next edition.

MORPHOLOGY

The mature female of the dracunculoid nematode *Dracunculus medinensis* (Linnaeus 1758) Gallandant, 1773 measures 500–800 × 1.0–2.0 mm. The mouth has a triangular oval opening surrounded by a quadrangular cuticularized plate, and an internal circle of four double papillae. The vulva opens halfway down the body but is nonfunctional in the mature worm. The uterus has an anterior and a posterior branch; it is filled with 1–3 million embryos and occupies the entire body cavity (pseudocoel), the gut being completely flattened (Cairncross et al. 2002).

Males recovered from experimental infections in animals measure 15–40 × 0.4 mm. The tail has 4(3–6) pairs of preanal and 4–6 pairs of postanal papillae; the subequal spicules are 490–750 μm long with a gubernaculum measuring about 117 μm. The males probably die in the tissues before the females mature but have only doubtfully been seen in human infections.

LIFE CYCLE

In the human body, each female worm takes about one year to mature and moves to the surface of the skin. It provokes a blister at the anterior end which bursts and leaves an ulcer through which about 5 cm of the worm is extruded, particularly after immersion in water (Figure 41.1a). Many thousands of larvae are released into the water where they can live for only a few days; for further development they have to be ingested by small freshwater crustacea (cyclops). The larvae molt twice in the body cavity and are infective in about 2 weeks. If cyclops are ingested in drinking water, released larvae penetrate the human intestinal wall and male and female worms mate in the connective tissues in about 3 months.

TRANSMISSION AND EPIDEMIOLOGY

Dracunculus infection still occurs in 12 countries of West and Central Africa: principally in Sudan, Ghana, and Nigeria but also in Benin, Burkina Faso, Cote d'Ivoire, Ethiopia, Mali, Mauritania, Niger, Togo, and Uganda (Cairncross et al. 2002) and with a recent isolated outbreak in Libya. The disease has been eliminated or has died out in Cameroon, Central African Republic, Chad, Guinea Bissau, India, Iran, Pakistan, Saudi Arabia, Senegal, and Yemen in recent years.

Dracunculiasis is typically a disease of rural communities that obtain their drinking water from ponds (or, formerly, in India, from large step wells) where cyclops can breed (Figure 41.2). In all areas, transmission is markedly seasonal and, in most parts of Africa, the maximum incidence coincides with the planting season, resulting in great economic hardship. In semi-desert (Sahel) areas of Africa (Burkina Faso, Mauritania, Niger, northern Nigeria, and Sudan), drinking water is

Figure 41.1 *Dracunculiasis:* **(a)** *foot of child with three worms emerging and being wound out on sticks (Courtesy of Dr Ahmed Tayeh);* **(b)** *secondarily infected and swollen knee of girl with guinea worm emerging*

obtained from ponds during the rainy season but from deep (safe) wells for the rest of the year when the ponds are dry. However, in the humid (Guinea) savanna regions of West Africa where rainfall exceeds 150 cm per year (Benin, Cote d'Ivoire, Ghana, southern Nigeria, and Togo) there is almost no transmission during the rainy season (July–September) when ponds turn into streams and cyclops densities are low because of the large volume and turbidity of the water. The life history of the parasite is well adapted to provide the maximum chances of transmission as the female takes almost exactly a year to mature and release its larvae.

Figure 41.2 *One of many large artificial ponds constructed in Nigeria for drinking water and agriculture and which are transmitting both dracunculiasis and schistosomiasis*

LOCATION IN HOST

One to many adult female worms emerge from the subcutaneous tissues, usually of the foot or lower limbs, but sometimes from any part of the body.

CLINICAL MANIFESTATIONS AND PATHOLOGY

In most patients, the first physical sign is the local lesion, accompanied by an intense burning pain usually relieved by immersion of the affected limb in water. The blister fluid is bacteriologically sterile and contains numerous white cells and larvae. In uncomplicated cases, the worm emerges from the subsequent ulcer over a few weeks and then the lesion rapidly heals. Thus, if there is only one worm present, patency will last for only 4–6 weeks. Unfortunately, secondary infection along the track of the worm in the tissues is very common, often with spreading cellulitis, and approximately 40 percent of patients will be totally incapacitated for an average of 6

weeks (Figure 41.1b). More serious and permanent damage can follow the bursting of a worm in the tissues or as the result of bacterial infection, e.g. ankylosis of joints in about 1 percent of cases or, occasionally, tetanus.

Dracunculiasis is unusual among infectious diseases in that the parasite does not appear to stimulate a protective response, so that the same individual can be reinfected year after year.

DIAGNOSIS

Clinical and parasitological diagnosis

Patients in an endemic area usually have no doubt of the diagnosis as soon as or even before the first signs appear. Local itching, urticaria, and a burning pain at the site of a small blister are usually the first signs of infection. The blister bursts in about 4 days and active larvae, obtained by placing cold water on the resulting small ulcer, can be recognized under a low-powered microscope.

Immunological diagnosis

Immunological methods are not useful in practice. Enzyme-linked immunosorbent assay (ELISA) and sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS PAGE)/western blotting worked well in one trial for patent infections. Detection of parasite-specific immunoglobulin (Ig) G4 might be able to diagnose prepatent infections possibly up to 6 months before emergence (Bapna and Renapurkar 1996).

TREATMENT

Surgery

Guinea worms have been wound out on sticks since antiquity (e.g. in the Rig Veda of about 1350 BC). Provided that bacterial infection or other complications have not occurred, regular winding out of the worm on a small stick, combined with sterile dressing and acriflavine cream, usually results in complete removal in about 4 weeks with little loss of mobility. Treatment should be commenced as soon after emergence as possible (Magnussen et al. 1994). Sometimes, worms can be seen and surgically removed before emergence while there is no tissue reaction against them.

Chemotherapy

There is no evidence that any chemotherapeutic agent has a direct action against guinea worms. However, many compounds, including thiabendazole, niridazole, metronidazole, mebendazole, and albendazole, have been reported as hastening the expulsion of worms and may act as anti-inflammatory agents (Muller 1971). Ivermectin had no action against pre-emergent worms (Issaka-Tinorgah et al. 1994).

THE ERADICATION CAMPAIGN

The eradication of dracunculiasis from the world was adopted as a sub-goal of the Clean Drinking Water Supply and Sanitation Decade (1981–90) and was formally endorsed by the United Nations World Health Assembly in 1986 and 1989. If the original aim of complete eradication by the end of 1995 had been achieved, this chapter would have been superfluous. However, the task is likely to take quite a while longer, particularly in the Sudan. Nonetheless, the prevalence and distribution of infection have diminished markedly in the last few years: worldwide there were about 3.5 million cases in 1986, 1 million in 1989 but only 46 000 in 2002. Disease has been eliminated from Asia with no cases reported from Pakistan since 1993, nor from India since 1997 (Cairncross et al. 2002). The situation in African countries is not so far advanced but active campaigns are being carried out in almost all endemic countries and some are at the stage of case containment (Figure 41.3). In Nigeria and Ghana for instance, new cases have reduced markedly since 1988, and in all African countries on average 56 percent of cases were contained in 2002 (i.e. all larvae were prevented from reaching ponds). In 2002, only 3 000 cases were reported from Nigeria and 4 900 from Ghana. In 37 countries where the disease used to be present in historical times, applications for certification of absence have been made.

The first priority has been to have accurate figures on the distribution and prevalence in each endemic country. Because infected persons rarely report to health clinics, passive surveillance is almost useless (identifying less than 3 percent of cases) and trained teams of community workers are required to visit each village and obtain the necessary information. These teams have to be carefully monitored and, when trained, can also be associated with other primary healthcare initiatives, such as control of malaria and diarrhea diseases and immunization campaigns.

Once active surveillance measures have been initiated, there are various possible interventions based on knowledge of the life cycle of the parasite.

The provision by governments and aid agencies of safe drinking water from tubewells is a priority in rural areas of Africa and Asia. The United Nations (International) Children's (Emergency) Fund (UNICEF) aimed to provide one borehole for every 200 persons in suitable geological regions by the year 2000. In some areas, traditional (usually hand built) draw wells can be equally effective and in all areas,

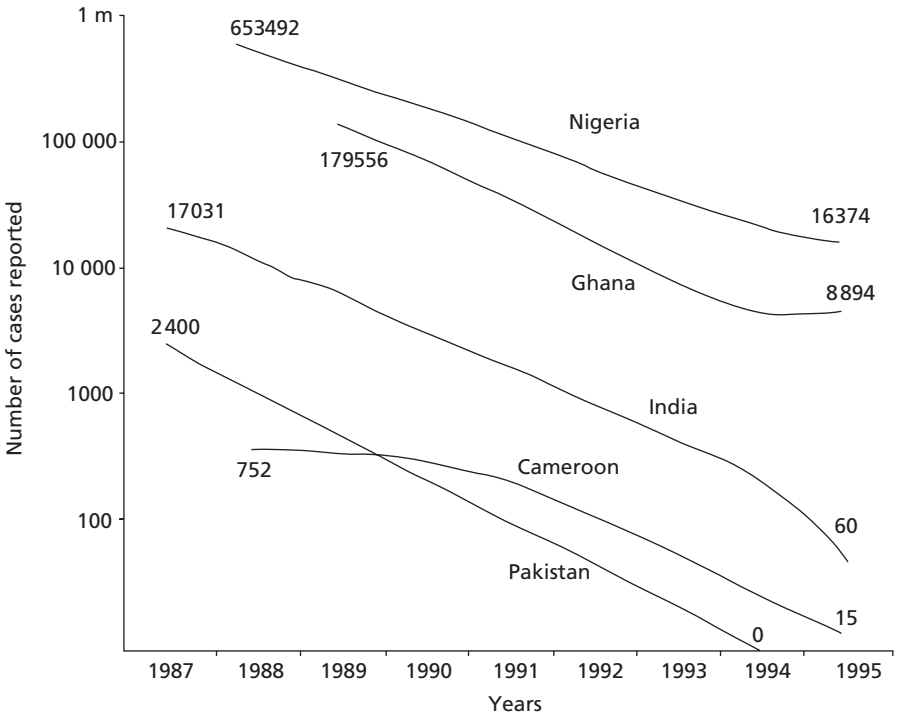

Figure 41.3 *Decrease in numbers of cases of guinea worm infection reported each year in five countries that have active campaigns (note log scale). The campaign in India started in 1980 (Sudan is not included).*

cisterns can be constructed for storing rainwater (Figure 41.4).

Health education interventions by local health workers form a very important component of any control or eradication campaign. Interventions being made include the following:

- Filtering or boiling all drinking water. Boiling water is not usually feasible because fuel is a scarce commodity but filters are playing an important role in all countries now mounting campaigns. The donation by the manufacturer of monofilament nylon nets, which are long lasting, have a regular pore size, are

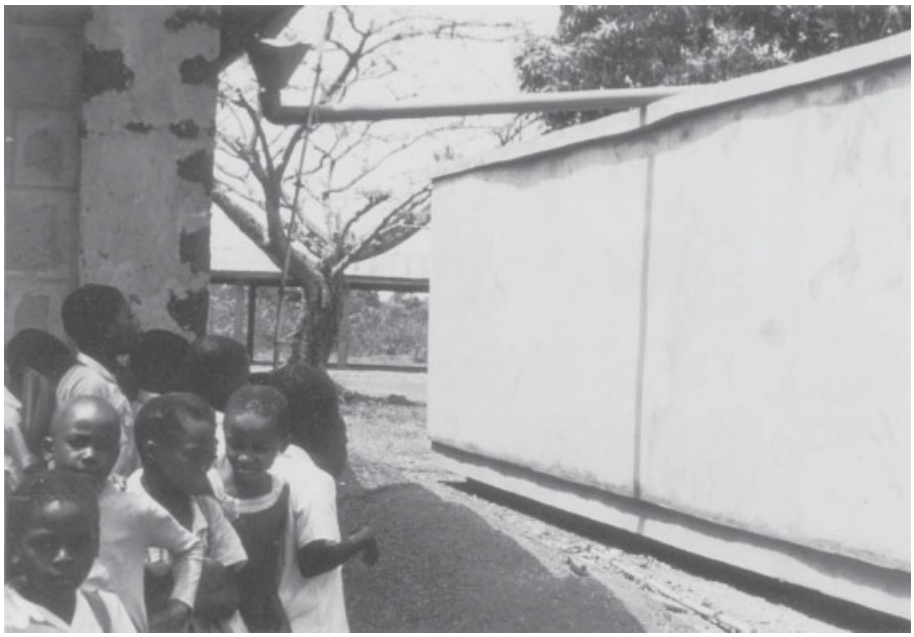

Figure 41.4 *Cistern built at a school in Nigeria to store rainwater for use during the dry season.*

easily washed and dry quickly, is proving of great help in sieving out cyclops. Health educators in all countries have been very successful in promoting the use of filters.

- Persuading or preventing infected persons with an emerging worm from entering the water source (containment). This is particularly important when prevalence has been greatly reduced (the current motto is 'detect every case, contain every worm'). Bandaging very early lesions can help to prevent subsequent immersion in the water.
- Treating water sources. The chemical treatment of ponds can prove a useful adjunct to other measures, particularly when there is only a low level of transmission remaining. The insecticide temephos added to ponds at a concentration of 1 ppm will kill cyclops for 5–6 weeks and has low toxicity to mammals and fishes. In areas with a long transmission season, it has to be added a few times a year. The amount of temephos estimated to be needed for total eradication in Africa has been donated by the manufacturer. The main problem is the amount of time that needs to be expended by trained technicians.

The disease was eliminated from Kenya and Senegal in 1996, and from Cameroon, Chad, and Yemen in 1999. There are very few cases left in all African countries apart from Ghana, Nigeria, and Sudan (49 000 cases in 2001 and provisionally 40 000 in 2002). The number of cases in Ghana and Nigeria is decreasing greatly each year but the future in Sudan is more uncertain (target eradication date of 2009).

ZOONOTIC ASPECTS

Female worms of the genus *Dracunculus* have been reported as emerging from a wide range of mammals and reptiles from many parts of the world, both endemic and nonendemic for the human disease. Those found in reptiles clearly belong to other species but the situation in regard to those in mammals is not clear. For instance, guinea worm is common in wild carnivores in North America and the species was named *D. insignis* by Leidy in 1858 but there is very little morphological evidence for separating this from the human species.

There have been two documented cases of clearly zoonotic infections, from Japan in 1986 and from Korea in 1926. In both cases, the patients had eaten raw freshwater fish that have been proved experimentally to be capable of acting as paratenic hosts.

In most highly endemic areas, occasional infections in dogs and donkeys with what is presumably the human parasite have been reported but there is no evidence that they have any part in maintaining transmission. The parasite can still be found in dogs in the formerly endemic areas of Tamil Nadu in India and the central Asian republics of the former Soviet Union but no new human cases have been reported, so it is not thought that this will be a problem once world eradication has been achieved.

Propagation of viruses in the laboratory	2	Conclusion	7
The properties of viruses	3	References	7

INTRODUCTION

Virus (Latin, from Greek φιοσ): a poisonous or slimy fluid. I have not called this chapter 'The history of virology' because it pertains almost entirely to viruses themselves, and not to the whole subject, which includes epidemiology, immune responses, pathogenicity, and many other topics. Such extended coverage would have demanded a chapter of inappropriate length. The survey deals mainly with the period from the end of the nineteenth century to about the end of the twentieth, and includes references to papers that are now seen to have provided points of departure for major advances.

THE FOUNDATIONS

The discovery of viruses

Bacteria were seen and cultivated before their association with disease was determined. By contrast, the nature of viruses was not elucidated until well after it was realized that certain diseases of plants and animals could be transmitted by an invisible infective principle that differed considerably from that of the known parasites. This discovery was made amid the ferment of ideas and experimentation on microbes that took place in the closing decades of the nineteenth century; the technical advance on which it was based was the invention by Charles Chamberland (1884), a colleague of Louis Pasteur, of a porcelain filter originally designed to sterilize drinking water. In 1892, Ivanowski in Russia showed that such a filter allowed passage of the agent that caused mosaic disease of tobacco. Somewhat diffidently, he suggested that the infective principle might be a toxin elaborated by bacteria, but did not pursue the matter. In 1898, Beijerinck independently made similar observations on this infection, but extended them much further (Beijerinck 1899, cited by Waterson and Wilkinson 1978: 27). To exclude the possibility that his porcelain filter was letting through a very small bacterium he used the then novel device of diffusing sap through agar gel, after which it still retained infectivity. He also observed that the agent multiplied only in dividing cells, and that it withstood desiccation but was inactivated by boiling. Having failed with the means at his disposal to demonstrate its particulate nature, he termed it a *contagium vivum fluidum*. In the same year, Loeffler and Frosch (1898), both associates of Robert Koch, reported passage of the agent of foot-and-mouth disease through a bacteria-retaining filter. They ruled out the idea of an inert toxin on the basis of the dilution factors involved, and concluded first, that the agent must be able to replicate, and second, that it must be smaller than the smallest bacterium then known, and thus beyond the resolving power of the best available microscopes. Although the great majority of viruses were beyond the bounds of resolution of the light microscope, Buist (1887) visualized one of the largest, vaccinia virus, after staining it with aniline methyl violet. He also assigned it the remarkably accurate measurement of 100–500 nm.

Propagation in tissue culture

By the end of the nineteenth century, viruses had been defined solely in terms of their infectivity, filterability,

and, as a result of Beijerinck's percipience, their requirement for living cells as a substrate for growth. Hitherto, viruses had been propagated only in intact animals or plants. Further progress demanded a much more simple and controllable system, the foundation of which was laid by Harrison (1906–7), who devised the first tissue culture, not for propagating viruses but for studying the growth of frog nervous tissue in clotted lymph. Steinhardt et al. (1913) exploited Harrison's technique to grow vaccinia in fragments of guinea-pig cornea embedded in clotted plasma. They could not demonstrate the virus directly in these preparations, but concluded from the results of serial subcultures that replication had taken place.

In 1928, Maitland and Maitland propagated vaccinia in suspensions of minced hens' kidneys. Their method was not widely used and its potential was not fully realized until a quarter of a century later, when flask cultures of trypsinized fragments of monkey kidney were used to grow poliovirus on a large scale for vaccine production.

Quantification

Guérin (1905) found that the number of vesicles produced by a suspension of vaccinia inoculated into scarified rabbit skin was roughly proportional to its dilution. This method was used by Steinhardt et al. (1913) in their tissue culture experiments, and was the precursor of many later and more accurate methods of assaying viral infectivity.

Host range and pathogenicity: effects on cells

The discovery of animal and plant viruses was soon followed by the finding of others that affected insects and bacteria. Oncogenic viruses were discovered by Ellerman and Bang (1908) and by Rous (1911), who respectively showed that a leukemia and a sarcoma of fowls could be transmitted by filterable agents. Another category, bacterial viruses (Twort 1915; d'Herelle 1917), was also to prove of the first importance, particularly for the study of viral replication and bacterial genetics.

In the early years of this century various workers described intracellular inclusion bodies in the tissues of animals and humans infected with viruses (e.g. rabies, *Cytomegalovirus*, and vaccinia). As the only obvious manifestation of viral activity within cells, inclusions were long the objects of intense study and speculation; they were categorized in terms of staining properties (eosinophilic or basophilic), location (intranuclear or cytoplasmic), and morphology (Cowdry 1934). They are now largely of academic interest.

Immune responses

It was long ago appreciated that certain infectious illnesses were followed by resistance to a second attack. This observation prompted the inoculation of material from cases of smallpox (variolation), which was for centuries practiced in eastern countries. The practice was associated with significant mortality (approximately 2 percent) and was eventually superseded by the use of cowpox as the result of astute observations in the eighteenth and early nineteenth centuries by Edward Jenner (1801) and by lesser-known figures such as Benjamin Jesty, a farmer in Dorset. The last two decades of the nineteenth century saw the pioneering work of Louis Pasteur and his associates on immunization against both bacterial and viral infections, the most dramatic example being rabies. Meanwhile, the mechanisms of immunity underlying these somewhat empirical observations were being unraveled in the laboratory. Elias Metchnikoff (1891) demonstrated the importance of phagocytes in combating certain bacterial infections, and thus founded the concept of cell-mediated immunity. This line of investigation was long overshadowed by work on humoral factors. Around the turn of the century, the quantitative and qualitative aspects of antigen–antibody reactions and their specificity were under intensive study by von Behring, Kitasato, Ehrlich, Landsteiner, and others; and Nuttall and Bordet discovered a heat-labile factor in blood, later to be designated complement, that was bactericidal in the presence of specific antibody. For a more detailed account of early research on immunology, see History, in the Immunology volume of this series.

The end of the beginning

By the end of the First World War, therefore, the foundations of virology had been laid. It had been established that viruses are much smaller than bacteria, and appeared to be capable of growing only in living cells, sometimes leaving evidence of their presence in the form of inclusion bodies. The main categories of viruses affecting respectively vertebrates, invertebrates, bacteria, and plants had been identified, the existence of oncogenic viruses was established, and the outlines of the immune response to viruses and other microbes were beginning to take shape.

PROPAGATION OF VIRUSES IN THE LABORATORY

Before discussing work on the properties of viruses, mention must be made of their propagation outside the intact animal, because such techniques are essential for studying them and most other microorganisms.

Chick embryos

Before the advent of antibiotics, tissue culture methods depended mostly on the growth of explants in clotted

plasma, and freedom from contamination was difficult to maintain. The removal of these constraints, which impeded both quantitative work and large-scale cultivation, was signaled in 1931 with the finding by Woodruff and Goodpasture that fowlpox virus inoculated on to the chorioallantoic membrane of 10–15-day-old embryos produced discrete lesions (pocks). Within the next few years other viruses, including herpes simplex, Newcastle disease virus of fowls, and louping ill virus, had been propagated in this way and infectivity titrations by the pock-counting method were being carried out (Burnet 1936). Later, the allantoic and amniotic routes of inoculation were used to grow a range of viruses (Beveridge and Burnet 1946), and some, notably yellow fever virus and influenza, were grown in large quantities for vaccine production.

Cell cultures

The tedious method of growing tissue fragments in plasma clot was quite unsuited to the propagation of viruses in any quantity. In the early 1950s, it was largely replaced by true cell cultures as a result of several technical advances, given impetus by the celebrated discovery of Enders et al. (1949) that poliomyelitis virus would grow in nonneural tissues. The technical advances were: (1) the introduction of antibiotics to control bacterial and fungal contamination; (2) the use of trypsin to obtain suspensions of single cells that could then be grown as monolayers on glass or plastic surfaces; and (3) the production of lines of cells that could be propagated by serial passage, which fell into two main groups. Some were derived either from malignant tumors, for example the HeLa line (Scherer et al. 1953), or from cells that had acquired malignant characteristics, including aneuploidy, during serial transfer, or after infection with certain viruses; these 'continuous' cell lines would grow indefinitely. Others were derived from normal tissues and retained their diploid karyotype for a limited number of transfers. Monolayer cultures had the great advantage that the effects of viruses in terms of cell destruction (cytopathic effect) could be readily observed by low-power microscopy.

Quantitative methods

The use of cell cultures greatly improved the accuracy of infectivity titrations, for which two principal methods were developed. The first was analogous to the counting of bacterial colonies obtained from a known dilution of suspension and, as we have seen, was applied to infectivity titrations of viruses that produced discrete lesions on the chick embryo chorioallantoic membrane. Suitably diluted suspensions of bacteriophage produced cleared areas ('plaques') in confluent lawns of bacteria on solid media, and, likewise, some animal viruses produced foci of destruction in cell monolayers overlaid with gel (Dulbecco and Vogt 1954). Because, in theory at least, each plaque resulted from the replication of one virus particle, the infectivity of the suspension could be accurately assayed as the mean of a number of replicate counts.

The second method was useful when plaque counting was impracticable. It depended on ascertaining the highest dilution of suspension producing a certain endpoint, for example the death of an animal or a cytopathic effect in a cell culture. The precision of the method was much enhanced by estimating the dilution producing the endpoint in 50 percent of the animals or cultures inoculated. The earliest and perhaps best known method for doing so was that of Reed and Muench (1938).

From about 1970 onwards, developments in rapid methods of nucleic acid and protein analysis contributed greatly to fundamental knowledge of the properties of viruses and to the diagnosis of viral infections. During the same period, the introduction of micromethods and automation made possible the use of techniques such as enzyme-linked immunosorbent assays (ELISA) for analyzing large numbers of specimens. Such methods progressively replaced the more cumbersome and less informative assays using, for example, complement fixation.

THE PROPERTIES OF VIRUSES

Physical characteristics

SIZE

Probably because of the difficulty of propagating them in the laboratory, research on the sizing of viruses by filtration and centrifugation was an important focus of attention until well into the 1940s.

In 1929, Elford described a method of making series of collodion membrane filters of known average pore diameter (APD); with the proviso that the conditions of filtration had to be carefully controlled, their availability greatly assisted the measurement of viruses. Thus, by 1940, the sizes of about 25 animal viruses, ranging from the enteroviruses (approximately 20 nm) to poxviruses (approximately 250 nm) had been measured with fair accuracy (see van Rooyen and Rhodes, 1940a). Such studies were further advanced by the use of high-speed centrifuges, notably of the Sharples and Svedberg varieties (reviewed by van Rooyen and Rhodes 1940b), to estimate size as a function of the sedimentation characteristics.

Centrifugation was also useful for purifying viruses and became more so with the introduction by Brakke (1953) of sucrose density gradients, in which particles within a mixture can be separated according to their

sedimentation rates. Later, cesium chloride and other salts were used with great success in high-speed centrifuges to separate viruses from contaminating material on the basis of their differing buoyant densities.

MORPHOLOGY

Until 1939, next to nothing was known about the structure of viruses because of the constraints imposed by the limited resolving power of light, even of short wavelengths in the ultraviolet range. In that year Kausche, Pfannkuch, and Ruska visualized a virus with the newly invented electron microscope (EM), in which beams of electrons travelling in a vacuum are focused on the object with electromagnetic fields. Given the then current interest in crystalline tobacco mosaic virus (TMV) (see Chemical composition: the role of the nucleic acids), it is not surprising that this was the first virus to be examined. Kausche and his colleagues (Kausche et al. 1939) employed the technique of shadow-casting, whereby the objects on the specimen grid were coated with gold particles generated by heating the metal in a vacuum; they defined the size of the crystals as about 25 × 300 nm.

After the interruption of the Second World War, new techniques were introduced to exploit the potential of the EM; they are well reviewed by Almeida (1984). In brief, shadow-casting revealed important morphological features of viruses, including the fact that some have an icosahedral structure. Negative staining, in which the background, but not the virus, is stained with an electron-dense salt of tungsten, uranium, or osmium, found wide application, not least in the diagnostic laboratory, and demonstrated that the outer surfaces of virus particles are composed of subunits. Methods were developed for cutting ultrathin sections in the 2-nm range which, alone or treated with labeled antibodies, yielded much information about virus–host-cell relationships.

These techniques, together with X-ray diffraction studies, showed that most viruses fall into one of two groups: the icosahedral viruses with so-called cubic symmetry; and those with helical symmetry, in which the outer subunits are arranged like the treads in a spiral staircase.

Chemical composition: the role of the nucleic acids

The demonstration by Stanley (1935), that TMV could be obtained in an apparently crystalline form, further stimulated the active, but ultimately sterile, debate on whether viruses are living entities. More importantly, it prompted study of the chemical composition of such preparations; and in 1937, Bawden and Pirie showed that they were not, as Stanley at first thought, pure proteins but also contained a nucleic acid, probably RNA. From this observation stemmed the realization that viruses consist of a nucleic acid contained within a protein coat; by the end of the decade, it was also clear that some viruses contain DNA rather than RNA. Following the demonstration by Avery et al. (1944) that the genetic information determining the type specificity of pneumococci resides in their DNA, Hershey and Chase (1952) confirmed the crucial role of nucleic acid in viral replication by showing that, after the attachment of bacteriophage T2, the DNA, but not the protein coat, enters the bacterial cell. A further major step was the demonstration by Gierer and Schramm (1956) and Fraenkel-Conrat (1956) that RNA in infective form could be extracted from TMV.

THE CONCEPT OF THE VIRION

Not long after Crick and Watson had solved the structure of DNA, they suggested that viral nucleic acid is protected by a shell of identical protein subunits (Crick and Watson 1956). This notion, based on the limited coding capacity of viral nucleic acid, proved essentially correct. All viruses were found to have this basic architecture (Klug and Caspar 1960; Caspar and Klug 1962), the nucleic acid being, with few exceptions, double-stranded DNA or single-stranded RNA. Caspar et al. (1962) proposed the following terminology: the complex of protein shell (capsid) and nucleic acid is the nucleocapsid; the mature nucleocapsid, surrounded in some viruses by an outer envelope, is referred to as the virion.

Replication

For well over half a century after their discovery, nothing was known of the way in which viruses reproduce themselves. From about 1940 onwards, however, research by Delbrück, Luria, Hershey, Lwoff, and many others elucidated the basic mechanisms. Much of the work was done with bacteriophages, which had the advantages over animal viruses of easy propagation in vitro, accurate quantification, and growth cycles measured in minutes rather than hours; considerable use was made of radiolabeling to trace the synthesis of nucleic acids and proteins. The mechanisms of viral attachment, penetration, and uncoating were defined, as was that of the coding of enzymic and structural proteins by messenger RNA.

By 1957, André Lwoff was able to crystallize the essential features that distinguish viruses from all other organisms: they are strictly intracellular and potentially pathogenic entities with an infectious phase, and (1) possess only one type of nucleic acid; (2) multiply in the form of their genetic material; (3) are unable to grow and undergo binary fission; and (4) are devoid of a Lipmann system of enzymes for energy production.

'Unconventional' viruses

Two groups of viruses or virus-like agents stand apart from the generality of animal viruses: these are the retroviruses and the prions.

RETROVIRUSES

The finding by Ellerman and Bang (1908) and Rous (1911) that certain malignancies of fowl are caused by a transmissible agent was followed by the observation that many others in birds and animals, both of the solid tissues and of blood, can be transmitted vertically, from parents to offspring, as well as horizontally. The oncogenic effects of the viruses concerned are characterized by unusually long incubation periods. Temin argued for many years that the persistence of these RNA-containing viruses was due to a DNA 'provirus' that had become integrated into infected cells. This was finally confirmed when it was discovered that their RNA is transcribed to a DNA copy by means of an enzyme, reverse transcriptase (Baltimore 1970; Temin and Mituzani 1970), so called because it reverses the usual flow of genetic information from DNA to RNA.

Fatal infections, also with long incubation periods but otherwise dissimilar, appeared among sheep in Iceland following the importation of Karakul sheep from Germany in 1933; known as maedi and visna, they respectively affected the lungs and central nervous system (Sigurdsson 1954a). Other viruses, the so-called 'foamy agents,' were first detected in monkey kidney cells used for polio vaccine production during the 1950s and later in the kidneys of other species, including humans; these agents appear not to cause disease.

The viruses concerned have now been grouped into the *Retroviridae* family. The insertion and integration of viral DNA (provirus) into the host-cell genome accounts both for the chronicity of these infections and for the oncogenic potential of many of the viruses in the family. Later, retroviruses were discovered that cause infections of humans, notably leukemias and acquired immunodeficiency syndrome, and viruses of other families, notably hepatitis B, were found to utilize reverse transcription during replication; but these developments are outside the scope of this chapter.

PRION DISEASES

For the past 200 years, a widespread disease of sheep and goats has been recognized that affects the central nervous system, has an incubation period of several years, and is always fatal; it is known as scrapie because the severe itching impels affected animals to rub against posts and fences. The disease could be transferred between sheep by injection of brain tissue (Cuillé and Chelle 1936); its transfer to mice (Chandler 1961) and hamsters, with an incubation period of less than a year, greatly facilitated experimental work. A similar disease, rida, was reported in sheep in Iceland (Sigurdsson 1954b), and such infections were later identified in other animals, notably cattle in the UK. All were characterized by, inter alia, severe neuronal degeneration and vacuolation (spongiform encephalopathy), and by the presence in the brain of tangles of fibrils (scrapie-associated fibrils (SAF)). Analogous infections were found in humans, in the form of Creutzfeldt–Jakob disease (Creutzfeldt, 1920; Jakob, 1921), Gerstmann–Sträussler–Scheinker syndrome, and kuru (Gajdusek and Zigas 1957), a now extinct disease of the Fore tribe in Papua New Guinea spread by endocannibalism.

The year 1986 saw the start of a major epizootic of bovine spongiform encephalopathy (BSE), first in the UK, and later in other countries, involving many thousands of cattle infected by meat and bone-meal (MBM) given as a dietary supplement; it was eventually brought under control by extensive slaughter and the banning of suspect foodstuffs. In 1995, two adolescents in the UK, and subsequently others, were diagnosed with a form of Creutzfeldt–Jakob disease whose agent was indistinguishable from that of BSE. These cases were characterized by their early onset, longer than usual time to death, amyloid plaques, and absence of the usual electroencephalographic changes. This syndrome is termed new variant CJD (nvCJD). The number of cases ran into three figures, but is now declining.

The causal agents of these infections differ in many respects from 'conventional' viruses and cannot be classified on similar criteria. They are very small and highly resistant to heat and ionizing radiation. Even so, they can reproduce themselves, and some, at least, can undergo genetic variation. Prusiner (1982) marshalled the evidence suggesting that these agents are protein and devoid of nucleic acid; he termed them prions (proteinaceous infectious particles). His view that they are an aberrant form (PrP^{Sc}) of a protein (PrP) normally found in the brain has now gained wide acceptance. The mode of reproduction is probably explained by repetitive conformational changes induced by PrP^{Sc} in the normal protein. (Weissmann 1991).

CLASSIFICATION OF VIRUSES

Now that the story of research on the properties of viruses has been described, it is appropriate to consider how they have been applied to viral classification. The early history of this topic was reviewed by Brown (1984); here, there is space to refer only to the main events.

The earliest attempts at grouping viruses were necessarily based on what they do rather than on what they are: the criteria included clinical effects, pathological changes, and tissue tropisms. The inadequacies of such systems were apparent, and in 1950 a Subcommittee on Virus Nomenclature under the chairmanship

of C.H. Andrewes was set up at the International Congress of Microbiology held at Rio de Janeiro; it recommended use of a system based on the physical, chemical, and antigenic properties of the viruses themselves, and allotted names to some of the better known (e.g. poxvirus, herpesvirus, myxovirus). In 1961, Cooper proposed, inter alia, the fundamentally important grouping by type of nucleic acid. Soon afterwards, Lwoff et al. (1962) put forward a universal system that has contributed much to the modern classification. The criteria were:

1 the type of nucleic acid (DNA or RNA);
2 the symmetry of the virus;
3 the presence or absence of an envelope;
4 the diameter of the nucleocapsid for helical viruses or the number of capsomeres for cubic viruses.

On the basis of these and other criteria, viruses are assigned to families (and sometimes subfamilies), genera, and species. Baltimore (1971) provided a basis for further refining classification that takes into account genome conformation and strategies for mRNA synthesis, characteristics that are being used on an increasing scale (van Regenmortel et al. 2000.

IMMUNIZATION AND ANTIVIRAL THERAPY

At the beginning of this chapter, I stated that it would not be possible to cover applied virology. Nevertheless, at a time when major successes are being scored by both virus vaccines and antiviral drugs, it is only right to include mentions of these topics, brief though they must be.

Viral vaccines

Smallpox vaccine was the first to come into general use and the first to eradicate an infectious disease worldwide (Fenner and Henderson 1988), the last natural case having occurred in Somalia in 1977. The conquest of smallpox is set fair to be repeated with other vaccines, notably poliomyelitis and measles. The development of viral vaccines reflects the advances in virological techniques over the past two centuries, ranging successively from animal inoculation to the use of chick embryos, cell cultures, and finally recombinant DNA technology (Table 1).

Antiviral therapy

Because of the intimate association between viruses and their host cells, the development of antiviral agents lagged behind that of compounds active against other microbes. Because the replication of viruses was not well understood, its basis was at first purely empirical and depended largely on random screening of many potentially useful compounds; the devising of compounds directed against specific target activities, such as attachment to the host cell, nucleic acid synthesis, and the release of mature virus, is of more recent origin.

An early development in antiviral therapy was the discovery by Isaacs and Lindenmann (1957) of interferon (IFN), a low molecular weight protein produced by cells in response to infection with viruses, some bacteria, double-stranded nucleic acids, and other biological compounds (see also Isaacs et al. 1957). Three classes of IFN (α, β, and γ) with differing properties are now recognized. The early finding that IFN inhibited a

Table 1 *Vaccines for human use developed in the past two centuries*

Decade in which introduced	Vaccine	Live (L) or inactivated (I)	Derivation
1800–1809	Smallpox	L	Animals
1880–1889	Rabies	I	
1940–1949	Yellow fever	L	Chick embryos
	Influenza	I	
1950–1959	Polio (Salk type)	I	Cell cultures
1960–1969	Rabies	I	Cell cultures
	Polio (Sabin type)	L	
	Measles	L

	Rubella	L	
1980–1989	Hepatitis B	I	Human plasma
	Hepatitis B	I	Yeast[a]
	Japanese B encephalitis	I	Mice or cell cultures
	Varicella	L	Cell cultures
1990–1999	Hepatitis A	I	Cell cultures

a) Genetically engineered antigen.

Table 2 *Examples of antiviral compounds developed since 1960*

Year[a]	Compound	Target	Viruses inhibited
1960	Methisazone	Ribonucleoside reductase	Poxviruses
1963	Amantadine/Rimantadine	Inhibits virus uncoating	Influenza A
1972	Ribavirin	Not yet fully defined	Respiratory syncytial virus; Lassa fever
1978	Acyclovir	DNA synthesis	Some herpesviruses
1985	Azidothymidine	DNA synthesis	HIV
1990	Saquinavir	Protease inhibitor	HIV (and probably others)

a) Approximate only. Indicates an early description rather than when the compound was first licensed for clinical use.

wide range of viruses raised hopes that it would be in the nature of a universal panacea for viral infections. This expectation was not fulfilled, but more recently IFN have proved useful in treating some cases of chronic hepatitis B. The large doses required can be produced by recombinant DNA techniques.

The precursor of all synthetic antiviral compounds was *p*-amino-benzaldehyde, 3-thiosemicarbazone (Brownlee and Hamre 1951), which inhibited vaccinia virus. A related compound, methisazone, appeared to have a prophylactic effect in smallpox contacts, but was rendered superfluous by the success of the vaccine eradication campaign. However, a more profitable approach was becoming apparent. By 1955, Matthews and Smith were able to write: 'There is a growing body of evidence suggesting that the genetic properties of viruses may reside largely in their nucleic acids, and a number of recent observations show that virus multiplication can be delayed by compounds which interfere with nucleic acid metabolism. As a class, analogues of the purine and pyrimidine bases may inhibit growth by a variety of mechanisms' (Matthews and Smith 1955). This prediction was fulfilled; the greatest achievements have in fact been the therapy and prophylaxis of herpesvirus infections with nucleoside analogs, at first idoxuridine (5-iodo-2′-deoxyuridine) and latterly acyclovir (9-(2-hydroxyethoxymethyl) guanine) (Table 2). Another such compound, zidovudine, has had a limited measure of success against infection with human immunodeficiency virus. It is, however, clear that our successors will regard this era as still part of the early history of antiviral therapy. The benefits of molecules designed to block specific receptors, drugs accurately aimed at defined targets within the replication cycle, synthetic antigens, DNA vaccines, and novel delivery systems lie still in the future.

CONCLUSION

The virologist will readily appreciate how much has had to be omitted from this brief account, but I hope that it will convey to the nonspecialist something of the many and complex strands that have combined to make the study of viruses such a leading influence in microbiology. From its beginnings, virology has provided a high degree of intellectual challenge that has attracted many leading minds, not least through its contributions to our knowledge of biological processes at the molecular level. The reader who wishes to study the fascinating story in more detail will find good accounts in the books by Lechevalier and Solotorovsky (1965) and Waterson and Wilkinson (1978).

THEORIES ON THE ORIGIN OF VIRUSES

Some fundamental questions such as the origin of life or the origin of viruses cannot be answered with any precision because the critical events occurred eons ago, and the questions do not lend themselves to direct experimental studies. There is no fossil record of viral sequences and even if molecular techniques enabled recovery of putative viral sequences from well-preserved fossils, it is likely that such sequences would be cryptic and difficult to relate to modern viruses because of their rapid evolution. Thus questions such as if there were (and how they were) viruses during the Cambrian explosion (a critical period from around 550 until about 485 million years ago in which a relatively rapid diversification of animal life occurred) are unlikely ever to be answered.

There have been several theories of the origin of viruses (reviewed by Joklik 1974; Luria et al. 1978; Botstein 1981; Atkins 1993):

- Viruses may be the descendants of primitive, precellular replicons that existed before the first cellular forms appeared on earth. These primitive replicons evolved to become dependent on cells for replication. Reverse transcription, which at some stage must have generated DNA from RNA, must have been active in producing primitive DNA viruses. According to this theory, the viruses we know today are the result of a long coevolutionary process of early viruses and cells which underwent a process of differentiation.
- In a completely different theory, viruses have never been descendants of simple replicons but, rather, they were the result of regressive evolution of complex microbial forms that displayed cellular organization and metabolism. A virus would be a parasitic, subgenomic form of a formerly free-living organism.
- Viruses originated from cellular DNA or RNA, or from subcellular organelles (such as mitochondria or chloroplasts). Part of the DNA or RNA could evolve to become decreasingly dependent on the cell, and eventually could include an extracellular step in its replication cycle.
- Viruses are as ancient as early cellular forms with which they have shared functional modules. The growing list of complete genomic nucleotide sequences of viral genomes and many unicellular and differentiated organisms (Mount 2001; Bushman 2002) suggests that all life forms and subcellular replicons share some basic structural and functional motifs. There are similarities between viral and cellular RNA structures and proteins involved in genome replication, proteolytic enzymes, and general patterns of genome organization and expression. No viral functions outstandingly different from similar cellular functions have been characterized. These findings of molecular genetics support the view that exchanges of functional modules, mediated by several forms of genetic recombination, together with mutation, contributed to coevolution of cells and a number of autonomous replicons, including viruses (Botstein 1981; Zimmern 1988; Gorbalenya 1995; Holland and Domingo 1998; Baranowski et al. 2001; DeFilippis and Villarreal 2001; Brown 2003).

Regardless of the details of early evolution of life on earth, and of the earliest origins of viruses, it is clear that cellular nucleic acids interact with, exchange with, and coevolve with, the DNA and RNA of viruses, plasmids, transposons, retrotransposons, and other mobile genetic elements (Hayes 1968; Monroe and Schlesinger 1983; Boeke 1988; Berg and Howe 1989; Harrison et al. 1991; Coffin 1992; Doolittle and Feng 1992; Syvanen 1994; Lodish et al. 1995; Bushman 2002). Novel viruses are among the 'new' life forms that evolve from such interactions, and the 'origination' of viruses is therefore a never-ending process (van Regenmortel et al. 2000). Their ubiquity, mobility, and capacity to recombine with cellular and other viral genetic elements put viruses (and other mobile elements) in the mainstream of all evolution on earth.

DNA viruses and RNA viruses may have had different origins or even if they shared a common ancestor they may have coevolved with cells in substantially different patterns. Examination of some distinctive features of DNA and RNA viruses may provide some insight into their evolutionary origins.

DNA viruses

DNA viruses may have arisen from combinations of cellular genes or by reverse transcription of RNA molecules. It is not yet clear, for example, whether a hepadnavirus (such as hepatitis B virus) was formerly a DNA virus that acquired a reverse transcriptase to allow replication via RNA transcripts, or if it was a retrovirus that evolved to encapsidate DNA replication intermediates instead of the RNA 'genome' (Doolittle and Feng 1992). Regardless of ultimate origins, any DNA virus has the potential to capture useful genes from cell chromosomes via DNA recombination (Cooper 2000).

DNA viruses as mobile DNA replicons

The distinction between DNA viruses and other autonomously replicating DNA replicons is sometimes tenuous. Plasmids, insertion sequences, transposons, and retrotransposons are mobile autonomous DNA replicons (Boeke 1988; Berg and Howe 1989; Coffin 1992; Doolittle and Feng 1992; Syvanen 1994; Bushman 2002) that resemble viruses in many respects, but they lack the capsid protein coats (and lipid/glycoprotein envelopes) that package viral genomes, protect them, and deliver them to appropriate receptors on susceptible host cells. It is this extracellular infectious stage that distinguishes viruses from other mobile DNA elements. Bacteriophage Mu is an example of a virus that is also a transposon (Berg and Howe 1989; Bushman 2002). It is a temperate phage, which, unlike phage lambda, can insert its DNA into numerous sites in the host bacterial chromosome. Copies of Mu DNA then transpose to many thousands of other chromosomal sites, thereby causing an enormous increase in mutation frequency. Mu therefore differs from the more common transposons because it encodes phage coat proteins which enable efficient transfer as a virus. As first suggested by Botstein (1981), it is likely that virus genomes undergo 'modular evolution' in which 'new' viruses can be created by a combination of genes or gene clusters derived from multiple sources, including chromosomes, defective viruses, plasmids, and mobile elements (Zimmern 1988; Baranowski et al. 2001).

Viroids and circular satellite RNAs

Of all the infectious viruslike mobile genetic elements, the viroids and related circular satellite RNAs (Maramorosch 1991; Robertson 1992; Semancik and Duran-Vila 1999) are the most primitive, and the most likely to have descended directly from primordial RNAs during the early evolution of life on earth. The viroids are small, naked RNA molecules several hundred nucleotides in length. They are covalently closed circular strands of RNA with extensive secondary structure, which replicate autonomously when introduced into susceptible plants, frequently causing characteristic signs of disease. They have intrinsic ribozyme self-splicing activity related to group 1 introns, and apparently replicate via a rolling-circle mechanism by interaction with plant cell transcription components. They do not require a protein coat for transmission and do not encode capsid proteins, so genome transmission and disease progression can be very slow, but effective. However, there are related satellite viruses (sometimes termed 'virusoids') that depend on coinfection of plants with an infectious helper virus to provide them with capsid proteins for efficient transmission (Vogt and Jackson 1999).

As yet, there are no known viroids (or viroid diseases) of animals or humans. Robertson (1992) has, however, pointed out the close similarity between human hepatitis D virus (delta (δ) agent) and viroids. Delta agent contains a self-cleavage viroid domain joined to a protein-coding domain that encodes the δ antigen. Furthermore, the δ agent RNA is a defective circular 'satellite' RNA that depends on coinfection with hepatitis B virus as a helper virus to provide capsid protein. This striking similarity to viroids or circular satellite RNAs led Robertson (1992) to postulate mechanisms of evolution of early self-replicating RNA genomes to form various 'conjoined' RNA replicons that ultimately evolved into mosaic DNA systems. These plausible speculations envisage early RNA replicons as progenitors of both present-day viroids and the intricate DNA-based life forms which now predominate. It should be noted that naked viroid RNAs and circular satellite RNAs thereby bear a relationship to RNA viruses similar to that of naked DNA replicons, including plasmids and

transposons, to DNA viruses. In both cases, viruses are distinguished as autonomously replicating nucleic acid mobile elements with the capacity to encode capsid proteins.

RNA viruses

RNA viruses are the most ubiquitous and diverse viruses, and they include two major groups, the riboviruses and the retroviruses. Both have very high mutation rates, and even clones (derived from a single parental genome) rapidly form diverse 'quasispecies' populations or 'mutant swarms.' The extreme mutability of RNA viruses and its biological consequences are discussed in detail in the sections on Mutation of virus genomes and Biological significance of virus quasi species.

RIBOVIRUSES

The ordinary non-retrovirus RNA viruses that replicate their RNA genomes entirely via RNA templates are called riboviruses. Their ultimate origins are uncertain, and are probably quite varied (see section on Theories on the origin of viruses). Some may be directly descended from early primordial RNA replicons, whereas others may have originated more recently by recombination, reassortment, or mutation of cellular RNAs. Regardless of their ultimate origins, it is likely that most riboviruses have exchanged RNA sequences with cellular RNAs (and other virus RNAs) and so their genomes are mosaics of sequences from multiple sources. 'New' riboviruses may frequently arise by recombination of genome segments from two or more different riboviruses. One example is western equine encephalomyelitis virus, which is a recombinant virus derived from parental genomes of eastern equine encephalomyelitis virus and from New World relatives of sindbis virus (Hahn et al. 1988; Weaver et al. 1994). Genetic recombination in all riboviruses may be common on evolutionary time scales (Strauss and Strauss 1988; Zimmern 1988). A striking laboratory example of the creation of a new virus by recombination of unrelated riboviruses was reported. Rolls et al. 1994, using recombinant DNA intermediates, created a remarkable infectious virus in which the surface glycoprotein of vesicular stomatitis virus (VSV) was expressed from a replicon of Semliki Forest virus (SFV). The SFV replicon encoded only the SFV replicase, and no structural proteins. When the VSV glycoprotein gene was inserted by molecular genetic techniques, infectious virus particles were formed by budding of plasma membrane vesicles containing the VSV glycoproteins enclosing RNA replicons. Because VSV is a negative-strand ribovirus and SFV is a positive-strand ribovirus, a highly unexpected 'hybrid virus' was created. This demonstrates not only that novel viral genome matings can be productive but also that enveloped infectious viruses can be much simpler than virologists had expected.

Chance may have played a role in the way functional modules have been linked together to form viable forms of viruses. Recently, G. Wertz and colleagues have altered the gene order of VSV and found that virtually all gene combinations tested yielded viable virus (Ball et al. 1999; Wertz et al. 2002). Therefore, founder events in processes of gene transfer and ligation may have exerted a definitive influence on the organization patterns of the viruses we see today.

RETROVIRUSES

Retroviruses, hepadnaviruses, and caulimoviruses share a unique capacity of their genomes to participate regularly as part of both the RNA and the DNA worlds. Although their ultimate origins are uncertain, it is probable that they have evolved from retroid transposable elements, as originally proposed in Temin's (1970) 'protovirus' hypothesis. There is a wide variety of 'viral' and 'nonviral' retrotransposons and related elements, including Gypsy, Copia, LINES and LINE-like elements, mitochondrial introns, mitochondrial retroplasmids, and bacterial reverse transcriptases (Boeke 1988; Temin 1989; Coffin 1992; Doolittle and Feng 1992; Bushman 2002; Brown 2003). The so-called 'viral' retrotransposons more closely resemble retrovirus genomes. All these elements have in common the presence of reverse transcriptase, but most lack envelope genes which allow cell-to-cell and organism-to-organism transmission as mature virus particles (virions). Other retroviral genes and domains such as long-terminal repeat (LTR), capsid protein, ribonuclease, integrase, and protease are variably present in various 'viral' and 'nonviral' retroid elements (Boeke 1988; Temin 1989; Coffin 1992; Doolittle and Feng 1992; Bushman 2002). Most of these retroid elements may represent little more than 'selfish' jumping genes which sometimes cause useful rearrangements of host cell DNA sequences and sometimes damage or kill their hosts via DNA alterations. At least some of them may, however, perform essential functions. For example, a LINE-like retrotransposon, TART in *Drosophila*, apparently preferentially retrotransposes to the termini of chromosomes in an essential process by which *Drosophila* telomeres are maintained (Sheen and Levis 1994). The telomerases involve reverse transcription to elongate chromosome termini (telomeres), a process required for indefinite periods of cell division in mammals (Kim et al. 1994; Cooper 2000).

Transposons have been found in the eukaryotic genomes sequenced to date such as the human genome, yeast, *Drosophila*, the worm *Caenorhabditis elegans*, mice, and several plant species (reviewed in Bushman 2002). Remarkably, 44 percent of the human genome is

made up of transposons or transposonlike elements. It is suspected that much of the 50 percent of the human genome that has not been assigned to a function, was likely contributed by mobile elements.

These findings provide strong evidence that retroid elements have been around for eons, that they can acquire additional genes, and that they can become retroviruses only if they acquire envelope genes to confer infectivity. Even now, 'new' retroviruses are continuously born (or reborn) by recombinational acquisition of cellular genes (e.g. proto-oncogenes in the case of some transforming retroviruses). Another source is the acquisition of genes from other retroviruses (e.g. LTR sequences, or altered *env* genes from proviruses in the case of mouse lymphoma virus) (Coffin 1992).

The origin of viruses is likely to remain a mystery for a long time. New observations may suggest one of the proposed mechanisms (condensed in the section on Theories on the origin of viruses) over another. In fact, multiple mechanisms may have participated in several origins of viruses at different stages of the evolution of life on earth. While it is plausible that viroids and other simple RNA elements may have evolved from primitive replicons (Semancik and Duran-Vila 1999; Vogt and Jackson 1999) it is hard to conceive the origin of complex DNA viruses (such as poxviruses, iridoviruses or herpesviruses with genomes of 130 000 up to 370 000 bp) as not being related to cells or cell organelles, either as a source of functional modules or as the starting point of a degenerative process. An interesting outcome of the development of tools to probe cellular and viral genome structures and their replication strategies is that they offer a number of plausible mechanisms (based on gene transfers, recombination, and mutation) for virus origins. Remarkably, these same mechanisms are acting on present-day viruses, and they can be observed experimentally as affecting not only virus evolution but also disease manifestations on the hosts they parasitize.

VIRUS EVOLUTION AND MECHANISMS INVOLVED

Because they can replicate rapidly with high yields of progeny, and readily mutate, recombine, and reassort their genomes, most viruses can exhibit great genetic plasticity and adaptability. This provides the possibility for extremely rapid evolution, but does not dictate constant rapid genome evolution. Viruses, like other living things, can have periods of relative evolutionary stasis, punctuated by periods of evolutionary disequilibrium and rapid genetic change (Holland 1992).

Recombination

Recombination affords rapid, major rearrangements of viral genomes, and this mechanism for evolution is widespread among DNA viruses and RNA viruses. Both homologous and nonhomologous recombination are very common, and the latter has the potential to produce quite extensive genome alterations and bizarre phenotypes.

DNA VIRUS RECOMBINATION

Mechanisms of DNA recombination and transposition have been widely studied, are well characterized (Kucherlapati and Smith 1988; Cooper 2000; Bushman 2002) and will not be reviewed here. Recombination or transposition allows DNA viruses to acquire new genes from other viruses; to integrate into, and excise from, host-cell chromosomes; to generate defective virus genomes and to rescue genes from them; and to capture host-cell genes or to transfer them to new host cells. In short, DNA virus genomes have available to them all the recombinatorial mechanisms extant in the DNA-based world, and this gives them the potential for profound genome rearrangements and for extensive genetic interactions with DNA-based hosts. Many DNA virus genomes contain genes that have been captured (or rescued) from earlier hosts. For example, the thymidine kinase (TK) genes of herpesviruses exhibit broad substrate specificity, and have apparently evolved from cellular deoxycytidine kinase enzymes (Harrison et al. 1991), whereas poxvirus TK genes were apparently derived from cellular TK genes (Boyle et al. 1987). Defective viruses produced by recombination are ubiquitous among DNA viruses and may often help shape their evolution by maintaining functional (and rescuable) gene modules. Botstein (1981) suggested that the product of virus evolution 'is not a given virus but a family of interchangeable genetic elements (modules) each of which carries out a particular biological function. Each virus encountered in nature is a favorable combination of modules. . . .' Exchange of modules allows the evolution of viral genes to occur within differing viral genomes, host chromosomes, defective viruses, plasmids, transposons, etc. Viral genes can not only associate with plasmids and episomes and other replicons, but they can also become episomes or plasmids (autonomous, noninfectious replicons). Examples are bacteriophage F1 selected for 'benevolent' interactions with host *Escherichia coli* (Bull and Molineux 1992) and Epstein–Barr virus (EBV) virus 'episomal' circular genomes within transformed (immortalized) B lymphocytes (Lindahl et al. 1976; Lawrence et al. 1988; Middleton et al. 1991; Kirchmaier and Sugden 1995). The 'benevolent' F1 plasmids eventually lost viral genes and infectivity, but replicated efficiently within host bacteria, and the EBV episome genomes in EBV-immortalized B cell lines are generally non-infectious or poorly infectious unless 'induced' (Weigel and Miller 1983).

RETROVIRUS RECOMBINATION

Retroviruses, of course, have the potential to recombine at the proviral DNA level (as for any other DNA).

However, they have the additional capacity to undergo recombination as a result of the tendency for reverse transcriptases to switch from one template to another (copy choice) during DNA chain elongation. This occurs at an extremely high frequency, is responsible for most retrovirus recombination events, and can play a major role in retrovirus evolution (Coffin 1992). Recent quantifications have estimated a minimum rate of 2.8 crossovers per replication cycle of a HIV-1-based vector system (Zhuang et al. 2002).

One of the most striking developments during the acquired immunodeficiency syndrome (AIDS) epidemic has been the discovery of the contribution of recombination to generate new variant forms of HIV-1 (Thomson et al. 2002). An increase of the number of circulating HIV-1 recombinants is likely to be influenced by higher frequencies of re-infections with different HIV-1 viruses as the AIDS epidemic advances, and geographical boundaries for HIV-1 subtypes become gradually fuzzier. Also, HIV-1 evolution is associated with an expanded mutant repertoire which increases the probability of producing recombinants with sufficient relative fitness (a measure of the relative replication capacity of a virus; see section on Biological significance of virus quasi species) to become dominant in infected individuals and to be transmitted.

RIBOVIRUS RECOMBINATION

Riboviruses can also exhibit very high rates of genome recombination due to frequent copy choice switching from one template RNA strand to another by RNA replicase. The RNA replicase carries the growing RNA chain to another RNA template and can align it precisely by base pairing. Therefore, most recombination is homologous ('legitimate') for positive-strand RNA viruses, which replicate their genomes as naked RNA (King 1988; Lai 1992; Wimmer et al. 1993; Nagy and Simon 1997). Such homologous recombination is clearly important for RNA virus evolution. For example, recombinants between different serotypes of poliovirus vaccine strains occur frequently in vaccinated humans and can be rather strongly selected in their intestinal tract (Kew et al. 1981; Minor et al. 1986; Minor 1992; Agol 2002; Dahourou et al. 2002). During picornavirus infections, average recombination frequencies in cell culture using selectable markers have been estimated in 10–20 percent of the progeny; recombination frequencies tend to decrease with the genetic distance between the parental genomes (King 1988; Lai 1992). Frequent homologous recombination helps to shape the evolution of numerous riboviruses such as coronaviruses (Lai 1992) and brome mosaic virus of plants (Rao and Hall 1990; Nagy and Bujarski 1995; Nagy and Simon 1997). Even though copy choice recombination is much more common than non-homologous ('illegitimate') recombination among positive-strand riboviruses (and retroviruses), non-homologous recombination can occasionally produce major genome changes of great evolutionary importance. For example, the coronavirus mouse hepatitis virus appears to have acquired its hemagglutinin-esterase gene by recombination with influenza C virus, a negative-strand virus (Luytjes et al. 1988). Mucosal disease variants of bovine viral diarrhea virus (BVDV), a positive-strand pestivirus, are cytopathogenic viruses often generated either by multiple mutations or by recombination of parental, nondefective, noncytopathogenic BVDV genomes with cellular mRNAs (Meyers et al. 1991; Tautz et al. 1994; Kummerer et al. 2000).

Negative-strand riboviruses, which replicate their genomes as ribonucleoprotein strands rather than naked RNAs, generally undergo homologous recombination much less frequently than positive-strand RNA viruses. Replicase template switching occurs frequently, but this nearly always produces nonhomologous recombination because the growing RNA strands, being ribonucleoprotein, are not able to anneal and align the growing RNA chain precisely on homologous segments of the new template (Barrett and Dimmock 1986; Roux et al. 1991). Recently, homologous recombination of the negative-strand RNA Tula virus has been described (Plyusnin et al. 2002). To what extent homologous recombination in nature occurs with negative-strand RNA viruses is not known, but the study by Plyusnin et al. (2002) has certainly opened prospects for interesting research. Recombination of negative-strand riboviruses regularly produces biologically important variant genomes, particularly defective interfering (DI) particles. These can exert significant modulatory effects on parental virus infections (Barrett and Dimmock 1986; Huang 1988; Roux et al. 1991). Occasionally, quite bizarre recombinants between cellular RNAs and viral RNA genomes arise. For example, when a 54 nucleotide segment of 28S ribosomal RNA was inserted into the hemagglutinin gene segment of influenza A virus (by recombination during growth in chick embryo cells), the resulting recombinant virus was much more virulent, causing systemic lethal infections in chickens (Khatchikian et al. 1989). Similarly, a number of isolates of potato leafroll virus have acquired a 119 nucleotide segment from plant chloroplast DNA (Mayo and Jolly 1991), and cell culture replication of well-characterized strains of poliovirus (Charini et al. 1994) and sindbis virus (Monroe and Schlesinger 1983) led to acquisition of a short ribosomal RNA segment and a tRNA, respectively. Thus, although major nonhomologous recombination events are generally infrequent in ribovirus evolution, they occur sufficiently often to have significant evolutionary effects. They might even influence the results of biotechnological manipulations in which resistance to virus is conferred on transgenic plants expressing viral mRNA segments. For example, recombination between a defective plant virus genome and a viral

mRNA transcript expressed in transgenic plants restored infectivity to the defective viral genome (Greene and Allison 1994).

Recombination may have two disparate effects in evolution. It may produce entirely new genome combinations from distant parental molecules such as the heterologous recombination events that led to influenza viruses with a fragment of ribosomal RNA (Khatchikian et al. 1989). This is an exploratory activity that may produce novel genome combinations, and only an extremely small fraction out of many unsuccessful trials are likely to produce high fitness virus (see section on Biological significance of virus quasi species). For example, the influenza recombinant was very virulent for chickens, but did not survive to represent an epidemiologically relevant threat for other hosts. This unique recombinant probably occupied a very high fitness peak surrounded by deep, low fitness valleys in other environments (Wright 1982; Domingo et al. 2001a). Recombination may have an opposite effect in the rescuing of viable gene combinations from debilitated parents. This conservative activity will often be mediated by homologous recombination, and it is one of the possible mechanisms to counteract fitness loss in RNA virus due to Muller's ratchet (see section on Biological significance of virus quasi species).

Reassortment of ribovirus genome segments

A number of riboviruses have segmented genomes either of single-stranded RNA (influenza viruses, arenaviruses, bunyaviruses, several plant viruses) or double-stranded RNA (reoviruses, rotaviruses). Their genomes consist of a number of specific segments, each of which encodes one or more gene products. Each specific segment must be included in a virion together with all other segments in order for that virion to be infectious and to replicate infectious progeny. As expected, the various genomic segments from genetically different (but related) viruses can reassort to produce reassortant viruses, a process equivalent to the reassortment of maternal and paternal chromosomes that occurs during meiotic gametogenesis in diploid eukaryotic organisms. Ribovirus gene reassortment occurs when two distinct viruses simultaneously infect the same cell(s). Gene reassortment can cause major genome alterations during evolution of segmented riboviruses. The most striking examples are the influenza A viruses. Both the 1957 Asian and the 1968 Hong Kong influenza pandemics began in south China. These 'new' human viruses arose by reassortment of gene segments apparently derived from circulating avian viruses and from circulating human virus sources. Domestic pigs were suggested as the probable hosts in which the reassortment events took place ('mixing vessels') (Gorman et al. 1992; Webster et al. 1992; Webster 1999; Wuethrich 2003). It is probable that the next major influenza A pandemic will emerge some time during the next few decades, and that it will be due to reassortment events occurring in swine or humans or another 'mixing vessel.' Influenza C viruses, which usually circulate as multiple, independently evolving lineages in humans, have also undergone gene reassortment in man (Peng et al. 1994).

Major gene reassortment events between avian and human influenza A viruses are rare. This is undoubtedly because the currently circulating gene segments are co-evolving (and selected) for optimal interactions with each other. Therefore, only rare events could create a new virus with optimally interacting gene segments derived from widely divergent sources. Reassortment is common; it is the low probability for efficient interactions among diversely derived gene segments that greatly restricts the emergence of new influenza A pandemics. Reoviruses and many other segmented riboviruses also readily undergo genetic reassortment of segments from related lineages, and similar principles apply (Ramig et al. 1983; Desselberger 1996). There is, for example, evidence for segment reassortment in nature among viruses related to hantavirus pulmonary syndrome (Li et al. 1995), and for interspecific segment reassortment in the evolution of cucumoviruses of plants (White et al. 1995).

Mutation of virus genomes

Mutation is the primary driving force for all evolution, and it occurs inevitably and inexorably in all life forms, including viruses. In the RNA viruses (both riboviruses and retroviruses), a combination of small genome size, high mutation rates, high virus yields and very rapid replication, can produce spectacular rates of evolution. DNA viruses apparently mutate and evolve at lower rates, but they can nevertheless be quite mutable and biologically adaptable.

MUTATION AND EVOLUTION OF DNA AND RNA VIRUSES

The mutation rates of DNA bacteriophages have been characterized much more thoroughly than have those of the DNA viruses of humans and animals. Drake 1969 estimated the mutation rate of *E. coli* bacteriophages λ and T4 to be about 2×10^{-8} substitutions per nucleotide, two orders of magnitude higher than that of the host bacterium. Although mutation rates vary widely at individual genome sites, Drake (1991) has shown that there is a rather constant rate of spontaneous mutations per genome per replication in DNA-based microbes (including bacteria, yeasts, molds, and three DNA bacteriophages). Their genomic mutation rates per replication varied only about 2.5-fold around an average value of 0.0033 mutations per genome per replication round. Because the genome sizes of these diverse

DNA-based microbes vary by thousands-fold, their average mutation rates per base pair also vary by thousands-fold. Drake (1993) later calculated the genomic rates of spontaneous mutation among RNA viruses (the only known life forms with RNA genomes) and found them to be consistently higher. Animal lytic viruses (riboviruses) and RNA bacteriophages have an average genomic mutation rate per replication in the neighborhood of one, and retroviruses average slightly (about ten-fold) lower genomic mutation rates (Drake 1993; Drake and Holland 1999). Over all, these calculations tell us that genomic mutation rates do not vary markedly. They are remarkably fixed for DNA-based organisms, and are also fairly constant, but higher for RNA-based life forms (riboviruses and retroviruses). Obviously, as Drake (1993) pointed out, evolutionary forces must be shaping genomic mutation rates.

Despite the quite constant nature of genomic mutation rates, there is enormous variation in the mutation rates per nucleotide, per genome replication. This difference arises from the huge variation in genome sizes among living cells and subcellular replicons (Drake 1991; Drake 1993). Complex DNA viruses such as the herpesviruses are replicated by a viral-coded DNA polymerase endowed with a $3'\rightarrow5'$ exonuclease proofreading activity to increase DNA copying fidelity (Hwang et al. 1997). Proofreading and postreplicative misincorporation-correcting activities have evolved to ensure the copying fidelity needed for maintenance of genetic information of complex DNA genomes. By contrast, RNA replicases and reverse transcriptases lack exonuclease proofreading activities, as evidenced by biochemical tests (Steinhauer et al. 1992; Cameron et al. 2002). RNA viruses have mutation rates in the range of 10^{-3} to 10^{-5} substitutions per nucleotide copied, expected from their small genome size (Batschelet et al. 1976; Eigen and Biebricher 1988; Drake and Holland 1999). These values exceed by several million-fold the base misincorporations rates of their eukaryotic hosts. A clear example of this was given by Gojobori and Yokoyama (1985), who showed that the Moloney murine sarcoma virus, a retrovirus of mice, evolves at a rate a millionfold higher than the rate of its integrated cellular homologue, c-*mos*. This allows (but does not necessitate) rates of RNA virus evolution to proceed millions of times faster than that of their animal and human hosts (Holland et al. 1982; Smith and Inglis 1987; Domingo et al. 1988, 1992, 2001a; Eigen and Biebricher 1988; Domingo and Holland 1994; Duarte et al. 1994).

Extremely high mutation rates generate 'mutant swarms' or 'quasispecies' populations of RNA viruses, and can provide great adaptability. This factor must be balanced against the inevitable high levels of lethality when the rates are too high. Eigen and Biebricher (1988) have reviewed results that show by computer simulation that when mutation rates increase they suddenly exceed an 'error threshold' at which there is a 'melting' of genetic information or a transition into 'error catastrophe.' They have proposed that RNA virus quasispecies generally adapt to the error threshold at which the misincorporations rate per nucleotide per replication will be in the neighborhood of $1/\nu$ where ν is the length (in bases) of the genome. This figure can vary somewhat, depending on a selectively factor for the most fit 'master' sequences within a quasispecies population (Eigen and Biebricher 1988). This threshold limit dictates that genomic mutation rates generally cannot exceed values of about one. Drake's (1993) calculations indicate that most RNA virus genomic mutation rates are in fact close to one. Strong chemical mutagenesis of RNA viruses (inducing high lethality in progeny) only slightly increases mutation rates in viable progeny (Holland et al. 1990). This indicates that RNA viruses are at or near their error threshold. As Eigen and Biebricher (1988) have pointed out, occasional, short duration violations of the error threshold can provide brief evolutionary advantages, but persistent violations are lethal for viral genomes.

One mechanism for radical mutational changes in RNA viruses is biased hypermutation (Cattaneo et al. 1988; Wain-Hobson 1992; Cattaneo 1994; Martínez et al. 1994; Meyerhans and Vartanian 1999). Biased hypermutation can produce long segments of viral genome in which certain bases are substituted in a regular, recurring pattern. There are two major mechanisms, one of which involves deamination mediated by cellular enzymes (Cattaneo 1994; Harris et al. 2003). The other mechanism involves reverse transcriptase errors in retrovirus replication due to biased deoxyribonucleotide triphosphate pool concentration (Wain-Hobson 1992; Martínez et al. 1994). Either can produce sudden, massive genome changes.

In general, most RNA viruses are life forms that replicate and evolve near the extreme limits of mutability and adaptability. Genomic mutation rates in the range around 0.1–1 dictate that even clones of riboviruses and retroviruses are quasispecies, or mutant swarms, rather than collections of identical virus genomes. This quasispecies nature of RNA virus populations has numerous biological consequences, some of which are outlined below.

BIOLOGICAL SIGNIFICANCE OF VIRUS QUASI SPECIES

First and foremost, quasispecies populations endow RNA viruses with enormous environmental adaptability and capacity for extremely rapid evolution (Holland et al. 1982, Holland et al. 1992; Domingo et al. 2001a). Mutations are immediately seen when an RNA virus starts replicating in a new host, as documented with recent emergences such as HIV-1 and the severe acute respiratory syndrome (SARS) coronavirus (Holmes and Enjuanes 2003; Marra et al. 2003; Rota et al. 2003).

Rates of evolution for RNA viruses are often in the range of 10^{-2}–10^{-4} substitutions per nucleotide site per year (Domingo and Holland 1994). During persistent infections of cattle with biological clones of foot-and-mouth disease virus (FMDV), rates of evolution approached 10^{-1} substitutions per site and year in the genomic region encoding capsid protein VP1. This is one of the largest evolutionary rates recorded and demonstrates the capacity for rapid genetic change of viral quasi species evolving in their natural hosts (Gebauer et al. 1988). In sharp contrast, rates of evolution for cellular genes have been estimated in 10^{-8}–10^{-9} substitutions per nucleotide and year (reviewed by Domingo and Holland 1994).

Certain regions of an RNA virus genome (and certain single-base sites) may be much less variable (more highly conserved) than others and therefore evolve at much slower rates. In any currently circulating human strain of influenza A virus, evolution is gradual, and virus surface antigens evolve much more rapidly than do internal proteins (Webster et al. 1992). Sequence comparisons among all influenza viruses, all rhabdoviruses or all viral reverse transcriptases show that, eventually, nearly all sites can undergo viable mutations. Influenza A virus strains apparently evolve much more slowly in birds than in humans, even though these human strains have been derived from avian sources (Webster et al. 1992). Similarly, many arthropod-borne RNA viruses such as alphaviruses evolve about an order of magnitude more slowly in nature than do most other RNA viruses (Weaver et al. 1992, 1994; Strauss and Strauss 1994). Presumably, adaptive constraints necessary for efficient replication in two quite different environments (animal and insect tissues) can limit the rate of arbovirus evolution. But it is the evolutionary adaptability of RNA viruses that allows insect vector–host transmission cycles to evolve in the first instance. With very few exceptions, viruses that infect both insects and animals (or insects and plants) are RNA viruses. Generally, only RNA virus quasi species have the diversity and adaptability to move readily back and forth between quite diverse selective environments. In a number of cases of evolutionary stasis of RNA viruses, evolutionary rates are in the range of 10^{-4} substitutions per nucleotide per year, still 10^4–10^5-fold more rapid than cellular genes (Domingo et al. 2001a). RNA virus populations can reach adaptive equilibrium with host species, and relative evolutionary stasis results, whereas the same virus genes and replication enzyme in a new host can be driven to disequilibrium and rapid evolution when introduced into different selective environments (Holland et al. 1982; Domingo et al. 1988, 2001a; Domingo and Holland 1994).

Wide variations in evolutionary rates (among different genomic regions or within the same region depending on epidemiologic features and time intervals between sequence determinations) are expected from quasi species dynamics. This is because perturbations of mutant spectra that lead to modifications of dominant sequences are unpredictable. Therefore, a 'molecular clock' will rarely operate during evolution of an RNA virus (Domingo et al. 2001a). Minimal requirements for the measurements of evolutionary rates are that a founder sequence and its time of appearance in nature be identified and that there is a proper reconstruction of the evolutionary pathways of its progeny (Hillis et al. 1996). But even these conditions will rarely yield a constant rate of RNA virus evolution in nature because the response of individual hosts to the infection will not be identical (Holland et al. 1992) and dominant sequences will not be renewed in a time-dependent manner but rather in an environment-dependent manner.

Quasi-species dynamics: fitness variations and molecular memory

Because of their rapid rate of replication, high mutation rates, frequently large population sizes, and their limited genome length, RNA viruses have a great capacity for exploration of sequence space. This refers to the total number of possible sequences theoretically available to a genome (Eigen and Biebricher 1988; Domingo et al. 2001a). A numerical approximation illustrates this point. A viral genome of 10 000 residues has a total of 3×10^4 possible single mutants, which is below the population size of many viral populations. By contrast, in a mammalian genome the number of possible single mutants is about 10^{10}, a value which is well above the population size of any mammalian species. An essential feature of sequence space is the high connectivity among its different points which facilitates 'walks' to high fitness points. Fitness is a measure of the relative replication capacity of a virus in a given environment. Fitness differences have been quantitated in vivo by infecting animals with two viruses which compete for replication (Carrillo et al. 1998) and ex vivo, by infection-competition experiments in cell culture using variant viruses from in vivo infections (Quiñones-Mateu and Arts 2002; Ball et al. 2003). Model studies in cell culture have shown that serial passages of large populations of viruses result in fitness gains when measured in that same environment (Novella et al. 1995a; Escarmís et al. 1999). By contrast, repeated plaque-to-plaque transfers (serial bottleneck events) of virus in cell culture result in fitness losses (Chao 1990; Duarte et al. 1992; Escarmís et al. 1996; Yuste et al. 1999). During large population passages, selection of the best adapted mutant distributions can occur, while upon plaque-to-plaque transfers genetic drift prevails with the random accumulation of mutations, and little opportunity for compensation of their deleterious effects. In this case Muller's ratchet operates (Muller 1964). However, the virus population size that leads to fitness gain or fitness loss depends on the initial fitness of the population. Low

fitness virus tends to gain fitness upon passage of modest population numbers while for high fitness viruses the usual large population passages may not be sufficient for fitness gain (Novella et al. 1995b, 1999).

One of the consequences of quasispecies dynamics as it affects fitness variations is that viruses may maintain a memory of their past evolutionary history, as documented with independent evolutionary lineages and genetic markers of FMDV in cell culture (Ruíz-Jarabo et al. 2000, 2002; Arias et al. 2001). When FMDV genomes that were dominant in a population were outcompeted either by revertants or superior variants, the proportion of the outcompeted genomes did not return to a basal level dictated by mutational pressure but, instead, remained at a significantly higher level termed memory level. Memory levels were dependent on the initial fitness of the dominant genomes destined to become memory, and this is in agreement with theoretical predictions of quasispecies dynamics (Ruíz-Jarabo et al. 2002). Genetic bottlenecks erase memory as expected from memory being deposited in minority components of an evolving quasispecies. Memory reflects the behavior of viral quasispecies as complex adaptive systems (Frank 1996), and may allow viral quasispecies to respond more readily to a selective constraint that has been previously experienced by the same population, provided no genetic bottlenecks intervened. The presence of memory shows that mutant spectra of viral populations may not be only a random distribution of variants but may also be structured according to evolutionary history. This has a number of implications for viral diagnosis, now under investigation (Domingo et al. 2003).

EFFECT OF MUTATIONS ON VIRAL PHENOTYPES

Very often only one, or a few mutational changes can allow a virus to gain virulence, change its tissue tropism, or become resistant to an antiviral drug, or a monoclonal antibody, etc. (Holland et al. 1982; Smith and Inglis 1987; Domingo et al. 1988, 1992, 2001b; Domingo and Holland 1992, 1994; Duarte et al. 1994). Compared with the average (consensus) genome sequence, a large RNA virus quasispecies population will potentially contain almost every possible single-base change (see section on Quasi-species dynamics: fitness variations and molecular memory) and many double- and triple-base change combinations required for significant biological changes, so population selection rather than further mutation will often be sufficient. This is clearly illustrated by a study of HIV-infected individuals in whom antiretroviral inhibitor-resistant mutants were already present in the complete absence of current or prior drug treatment (Nájera et al. 1995). Following antiviral drug treatment of influenza-infected (Hayden and Hay 1992) or HIV-infected (Richman 1992) individuals, a substantial proportion of drug-resistant variants can emerge within days or a few weeks. Use of additional antiretroviral inhibitors has not ceased to enlarge a list of single and multiple mutations in the reverse transcriptase and protease of HIV that confer various levels of resistance to one or several inhibitors due primarily to mutation but also to recombination. This manifestation of adaptability of HIV constitutes a major drawback for the control of AIDS (Coffin 1995; Cabana et al. 1999; Menéndez-Arias 2002). Inhibitor-resistant mutants of other RNA viruses are also readily selected, as expected from high mutation rates and quasispecies dynamics (Domingo et al. 2001b).

Mutations in structural and nonstructural viral proteins may alter host-cell tropism and host range, with implications for viral disease emergence and re-emergence (Baranowski et al. 2001). Because of a frequent overlap between receptor-recognition sites and antigenic sites located on the surface of viral capsids and envelopes, a coevolution of host-cell tropism and antigenicity can take place (Stewart and Nemerow 1997; Baranowski et al. 2001), a concept first described with influenza virus (review by Skehel and Wiley 2000).

Large population passages of FMDV in cell culture offer a striking example of phenotypic modification resulting in expansion of host-cell tropism, with the use of integrins, heparan sulfate, and a third unidentified entry pathway to infect even the same cell type (reviewed by Baranowski et al. 2001; Airaksinen et al. 2003). Recent evidence suggests that antigenic variation that affects integrin recognition may be operating in vivo, again a demonstration of the adaptive potential of viral quasispecies within natural hosts (Tami et al. 2003; Zhao et al. 2003).

VIRUS EVOLUTION AND NEW ANTIVIRAL STRATEGIES

The Darwinian principles of genetic variation, competition, and selection that dominate biological evolution underlie several problems of disease control (antibiotic resistance in bacteria, drug resistance in eukaryotic pathogens, heterogeneity of tumor cells and metastasis, etc.) (review by Domingo et al. 2001a). Difficulties are even greater for the control of diseases associated with some genetically and antigenically highly variable viruses, and no effective preventive vaccines or therapeutic designs have yet been developed for important diseases such as AIDS or hepatitis C infections.

A new antiviral design based on the concept of error catastrophe (Eigen and Biebricher 1988; Eigen 2002) is under intensive investigation. For any complexity (amount of genetic information) hereditarily transmitted, there is a maximum error rate compatible with the maintenance of genetic information. Experimental evidence for the existence of an error threshold has been obtained with a number of RNA viruses including

poliovirus (Holland et al. 1990; Crotty et al. 2000, 2001), VSV (Holland et al. 1990; Lee et al. 1997), FMDV (Sierra et al. 2000; Pariente et al. 2001, 2003; Airaksinen et al. 2003), hepatitis GBV-B virus (Lanford et al. 2001), hantavirus (Severson et al. 2003), lymphocytic choriomeningitis virus (LCMV) (Grande-Pérez et al. 2002; Ruiz-Jarabo et al. 2003; Baranowski et al. 2003), and HIV (Loeb et al. 1999; Loeb and Mullins 2000). Interestingly, the antiviral nucleoside analogue ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) has been shown to be mutagenic for a number of RNA viruses (Crotty et al. 2000, 2001; Lanford et al. 2001; Airaksinen et al. 2003; Severson et al. 2003). Its pharmacologically active ribavirin triphosphate form is a substrate for some viral RNA-dependent RNA polymerases (Crotty et al. 2000; Maag et al. 2001; Graci and Cameron 2002). Ribavirin is used clinically to treat some viral infections, including hepatitis C virus infections in combination with interferon. Therefore, it is possible that some of the antiviral effects already documented for ribavirin in clinical practice were exerted through the transition of viral replication into error catastrophe.

An encouraging result regarding the potential application of an error catastrophe-based antiviral approach has been obtained by de la Torre and his colleagues (Ruiz-Jarabo et al. 2003) by showing that administration of the mutagenic base analogue 5-fluorouracil to mice prevented the establishment of a persistent infection with LCMV in mice. This constitutes a proof of principle of the feasibility of an error catastrophe-based approach as an antiviral strategy.

This chapter has shown that in addition to the fascinations and mysteries of virus origins and their evolution that we can observe today, a knowledge of the mechanisms underlying virus evolution has important implications for the understanding of viral disease and for the design of better strategies for their control. This is an enlightening demonstration on how basic research may lead to practical applications in the most unexpected ways.

THE FILTERABILITY OF VIRUSES

The first evidence that viruses are infectious, disease-causing agents different from pathogenic bacteria was obtained by filtration experiments with Chamberland filters. These bacteria-retaining filters which had been used by Pasteur to remove pathogenic microorganisms from water were used by Dmitri Ivanovsky in his classical studies of tobacco mosaic disease published in 1892. Ivanovsky showed that when sap from a diseased tobacco plant was passed through the filter, the filtrate remained infectious and could be used to infect other plants. The same experiment was repeated in 1898 by Beijerinck who again showed that the filtered tobacco sap was still infectious. Beijerinck went further and established that the infectious agent was able to diffuse through several millimeters of an agar gel, from which he concluded that the infection was caused not by a microbe but by what he called a *contagium vivum fluidum* or contagious living liquid. He called the agent which reproduced itself in the plant, a virus. During the same year, Loeffler and Frosch who were investigating foot-and-mouth disease reported that although the causative agent passed through a Chamberland-type filter, it did not go through a Kitasato filter which had a finer grain than the Chamberland filter. From this result, Loeffler concluded that the virus was a corpuscular particle and not a soluble agent as claimed by Beijerinck.

Although all historical accounts of the beginnings of virology refer to the work of Ivanovsky, Beijerinck, and Loeffler, there is disagreement among various authors about who should be credited with the discovery that viruses were a new type of infectious agent (Lvov 1993; Bos 1995; Witz 1998). This is an interesting debate since it concerns the question of what is a scientific discovery. Although Ivanovsky was clearly the first one to show that the agent causing the tobacco mosaic disease passed through a bacteria-retaining filter, all his publications show that he did not grasp the significance of his observation. He actually believed that the filter he used might have had fine cracks and that small spores of a microbe might have passed through the filter. More than 10 years after his initial observations he remained convinced that he was dealing with a bacterium rather than with a new type of infectious agent (Bos 1995). Beijerinck on the other hand, realized he was dealing with something different from a microbe but he thought that the virus was an infectious liquid and not a corpuscular particle as claimed by Loeffler (Witz 1998). Only Loeffler correctly concluded that the virus causing foot-and-mouth disease was a small particle stopped by a fine-grain Kitasato filter. The debate about who should be considered the founder of virology may be settled only if it is accepted that, in order to make a discovery, it is not sufficient to make a novel observation (i.e. the filterability of an infectious agent) but that, in addition, it is also necessary to interpret the observation correctly (Root-Bernstein

1989). Good science does not consist only in making new observations or collecting new data but it requires also unbiased, imaginative thinking which enables the scientist to arrive at the correct interpretation of his experimental findings. Loeffler's interpretation of his filtration experiments came the closest to the modern concept of a virus. However, it was only the work of William Elford with graded collodion membranes, done more than 30 years later, which established that different viruses had particle diameters of 20–200 nm (Grafe, 1991). The actual morphology of virus particles was finally elucidated only when the particles could be visualized by electron microscopy.

THE NATURE OF VIRUSES

At the beginning of the last century, viruses were characterized only by negative features, i.e. they were not identifiable by light microscopy, they could not be cultured on conventional bacteriological media, and they were not retained by filters used for sterilization (Grafe 1991). The perception of what is a virus changed dramatically in 1935 when Wendel Stanley showed that tobacco mosaic virus could be crystallized. This seemed to indicate that an infectious virus was a chemical molecule rather than an organism and it stimulated an intense interest in viruses as entities at the borderline between chemistry and biology. Many scientists became fascinated with viruses 'as living molecules.' This led physicists like Max Delbrück to turn to the study of bacteriophages because these viruses were more suitable for the quantitative analysis of virus multiplication. A reductionist, chemical approach to the study of biology was also stimulated by Erwin Schrödinger's book *What is life* published in 1945. Viruses were increasingly studied by physicochemical techniques and these studies contributed significantly to the development of molecular biology (Grafe 1991).

As our knowledge of the biochemistry of virus multiplication increased, it became clear that viruses depended for their multiplication on the protein-synthesizing and energy-producing systems of the host cell. Viruses were recognized to be subcellular infectious agents that, at one stage of their growth cycle in the infected cell, were reduced to their nucleic acid component. The virus particle or virion appeared simply as one stage of the virus life cycle. The virion was seen to protect the viral genome from degradation by nucleases and ultraviolet radiation and to allow the infectious agent to be transferred to a new host.

Whether or not viruses should be regarded as living organisms was regarded by some to be only a matter of taste. The question was sidestepped by Lwoff (1957) who declared that 'viruses should be considered as viruses because viruses are viruses.' However, it was generally accepted that viruses belong to biology since they possessed some of the properties of living systems, such as having a genome and being able to adapt to particular hosts and biotic habitats. On the other hand, viruses do not possess some of the essential attributes of living systems, such as the ability to capture and store free energy, and as a result they lack the characteristic autonomy that arises from the presence of a set of integrated, metabolic activities. Viruses are replicated through the metabolic activities of infected cells and they become part of a living system only after they have infected a host cell. The consensus among biologists at present is that the simplest system that can be said to be alive is a cell. The individual macromolecules and organelles found in a cell are not considered to be alive and there is indeed little justification for regarding viruses as living microorganisms. They are nonliving, infectious entities and they can be said, at best, to lead a kind of borrowed life (Van Regenmortel 2000a). According to D.J. McGeoch, viruses can be described as 'mistletoe on the Tree of Life' (Calisher et al. 1995).

The distinction between viruses and various types of organisms is highlighted when the functional roles of proteins present in viruses and in unicellular and multicellular organisms are compared. When proteins are classified in three broad, functional categories corresponding to energy utilization, carriers of information, and communication mediators, the proportion of each protein class found in viruses differs markedly from that found in living organisms (Tamames et al. 1996; Patthy 1999). Viruses have the highest proportion of proteins involved in information processes, i.e. in the control and expression of genetic information, and they have very few proteins of the energy and communication classes (Figure 1). This distribution obviously reflects the fact that viruses utilize the host cell's metabolic machinery and rely entirely on the energy supply system of the host they infect. By contrast, bacteria have the highest proportion of proteins of the energy

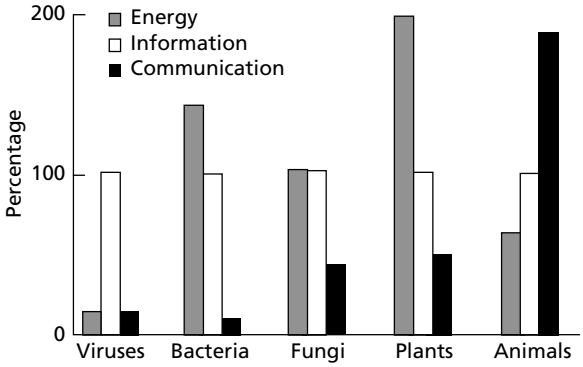

Figure 1 *The proteins of viruses, microorganisms, plants, and animals have different functional roles. The vertical bars represent the proportion of proteins in the categories of energy utilization and carrier of information relative to those in the category of mediator of information. Viruses have the highest proportion of proteins involved in information processes, i.e. in the control and expression of genetic information (from Patthy 1999).*

class involved in small molecule transformations whereas animals have a high proportion of proteins associated with intra- and intercellular communication (Figure 1).

VIRUSES SHOULD NOT BE CONFUSED WITH VIRUS PARTICLES OR VIRIONS

A virus is an elementary biosystem that replicates as an intracellular parasite in its host cell. During its multiplication cycle it takes on various forms and manifestations, for instance as a replicating nucleic acid in the host cell. One stage in the so-called 'life cycle' of a virus corresponds to the virus particle or virion which can be characterized by various intrinsic, structural, and chemical properties such as size, mass, chemical composition, etc. A virus, on the other hand, possesses, in addition, various relational properties that exist only by virtue of a relation with other objects such as a host or a vector. Some of these properties, for instance the replication cycle, are emergent properties that are possessed only by the system as a whole and are not present in its constituent parts. A virus should thus not be reduced to the physical constituents and chemical composition of a virion and it is necessary to include in its description also the functional activities that become actualized only inside the host as well as a variety of other biotic interactions (Van Regenmortel 2000a). Confusing the entity 'virus' with virion is similar to confusing the entity 'insect' with either a pupa, a caterpillar or a flying moth or butterfly. It is unfortunate that, in the scientific literature, virions are often referred to as the virus, for instance when one talks of 'the picture of the virus' or of 'the process of purifying the virus.'

VIRUS CLASSIFICATION AND NOMENCLATURE

The earliest attempts to classify viruses were based on the type of diseases they caused and the names given to the causative viruses were derived from the symptoms of the diseases and the hosts and organs that were infected. By the end of the 1950s, enough information on some types of virus particles had been gathered to allow the recognition of groups like the herpesviruses, the myxoviruses, and the poxviruses as well as several groups of elongated plant viruses. Following the development of the negative staining technique for observing virions in the electron microscope (Brenner and Horne 1959), it became relatively easy to establish the morphology of virus particles also in crude extracts. This in turn enabled the placement of viruses in genera and families according to virion morphology and stimulated the development of the Lwoff et al. (1962) scheme of virus classification. This hierarchical system was based on the assumption that the most important characteristics for classifying viruses were nucleic acid type and virion morphology. Although this scheme was initially criticized because the choice of criteria was deemed to be arbitrary, the attempt to replace it by an Adansonian system that gives equal weight to a large number of different characteristics was short-lived (Matthews 1983). Properties such as the size of the genome and the strandedness and polarity of the nucleic acid are stable properties since they determine the viral genome expression strategy and cannot be altered without being lethal for the virus. Likewise, the structural elements that build up a virion cannot undergo major changes without resulting in lethal instability of the virion.

The 63 virus families recognized at present (Van Regenmortel et al. 2000b) were demarcated on the basis of the nature of the viral genome, the strategy of replication used by the virus, and the structure of the virion. The family level in the taxonomic hierarchy has changed very little over the years, the main changes being the addition of more families. As new types of viruses were discovered in the families *Poxviridae*, *Herpesviridae*, *Parvoviridae*, and *Paramyxoviridae*, subfamilies have been introduced that group genera possessing certain common features.

In recent years, three virus orders representing groupings of families of viruses that share common characteristics have been created (Fauquet 1999). The order *Mononegavirales* comprises the families *Bornaviridae*, *Filoviridae*, *Paraxymoviridae*, and *Rhabdoviridae* that contain viruses with similar replication strategy. The order *Caudovirales* comprises the families *Myoviridae*, *Podoviridae*, and *Siphoviridae*, consisting of tailed, double-stranded DNA bacteriophages. The third order *Nidovirales* comprises the families *Coronaviridae*, *Arteriviridae*, and *Roniviridae*.

Viral families are subdivided into genera on the basis of characteristics that differ from one family to another, for instance differences in genome size and organization, virus replication strategy, vector transmission, etc. In some cases, when it is not clear whether a group of viruses placed in a genus should be included in an existing family or not, the corresponding genus is given the status of unassigned or floating genus.

The names of orders, families, subfamilies, and genera are latinized and written in italics with a capital initial letter and with the endings – *virales* for orders, *viridae* for families, *virinae* for subfamilies and *virus* for genera.

The families and unassigned genera of viruses that have been recognized up to July 2002 are listed in Table 1.

THE INTERNATIONAL COMMITTEE ON TAXONOMY OF VIRUSES

The authority on matters concerning virus classification and nomenclature is the International Committee on Taxonomy of Viruses (ICTV), which is a Committee of

Table 1 *Families and unassigned genera of viruses*[a]

Family or unassigned genus	Morphology of virus particle	Host
The dsDNA viruses		
Myoviridae	Tailed phage	Bacteria
Siphoviridae	Tailed phage	Bacteria
Podoviridae	Tailed phage	Bacteria
Tectiviridae	Isometric	Bacteria
Corticoviridae	Isometric	Bacteria
Plasmaviridae	Pleomorphic	Mycoplasma
Lipothrixviridae	Rod-shaped	Archaea
Rudiviridae	Rod-shaped	Archaea
Fuselloviridae	Lemon-shaped	Archaea
'SNDV-like viruses'	Droplet-shaped	Archaea
Poxviridae	Pleomorphic	Vertebrates/Invertebrates
Asfarviridae	Spherical	Vertebrates
Iridoviridae	Isometric	Vertebrates/Invertebrates
Phycodnaviridae	Isometric	Algae
Baculoviridae	Bacilliform	Invertebrates
Nimaviridae	Rod-shaped	Invertebrates
Herpesviridae	Isometric	Vertebrates
Adenoviridae	Isometric	Vertebrates
Rhizidiovirus	Isometric	Fungi
Polyomaviridae	Isometric	Vertebrates
Papillomaviridae	Isometric	Vertebrates
Polydnaviridae	Rod, fusiform	Invertebrates
Ascoviridae	Reniform	Invertebrates
The ssDNA viruses		
Inoviridae	Filamentous	Bacteria
Microviridae	Isometric	Bacteria
Geminiviridae	Isometic	Plants
Circoviridae	Isometric	Vertebrates
Anellovirus	Spherical	Vertebrates

a) Van Regenmortel et al. 2000a.

the Virology Division of the International Union of Microbiological Societies (IUMS). This Committee was established in 1966 at the International Congress for Microbiology held in Moscow and was initially called the International Committee on Nomenclature of Viruses. A few years later, the name of the Committee was changed to International Committee on Taxonomy of Viruses. The membership of ICTV comprises the 18 members of its Executive Committee, a number of Life members, over 40 National members and the members

of its specialist subcommittees (Mayo and Fauquet 2000). The ICTV operates through six subcommittees responsible for Bacterial Viruses, Fungal Viruses, Invertebrate Viruses, Plant Viruses, Vertebrate Viruses, and an electronic Virus Database [the ICTV database (ICTVdB)]. The subcommittees coordinate the work of about 60 Study Groups comprising more than 500 virologists representing all areas of virology. The current membership of the ICTV is listed at the ICTV web site (www.ncbi.nlm.nih/ICTV).

The activities of ICTV are regulated by statutes approved by the Virology Division of IUMS and by an International Code of Virus Classification and Nomenclature (Mayo and Horzinek 1998). The International Code requires that virus classification and nomenclature must be international and uniformly applicable to all viruses infecting animals, plants, and microorganisms.

Although the virus classification system employs the hierarchical levels of order, family, subfamily, genus, and species, it is not obligatory to use all levels of the taxonomic hierarchy. Most virus species are classified into genera and most genera are classified into families. When it is uncertain to which genus a virus species should be allocated, even though its classification in a family is clear, the species is classified as an unassigned species of that family. If it is not clear to which family a genus belongs, it remains an unassigned genus. In its effort to develop an internationally agreed taxonomy for all viruses, the ICTV relies on guidance from individual Study Groups composed of recognized experts in each area of virology. However, any recommendations made by Study Groups are first evaluated by the subcommittees and Executive Committee of ICTV for their acceptability to the virological community in general. The ICTV Executive Committee then prepares taxonomic proposals for ratification by the full membership of the ICTV, either by post or at plenary sessions held during the triennial International Congresses of Virology. Recently the Executive Committee of ICTV has started to use the ICTVnet to allow more extensive consideration of proposals by Executive Committee members prior to an Executive Committee meeting. This procedure was extended to allow a wider consultation with the virological community than was possible previously. The new procedure goes through several stages of discussion, modifications, and public scrutiny and has been described in detail (Mayo et al. 2003).

At regular intervals, the ICTV publishes reports which represent the state of virus taxonomy and nomenclature at the time of publication. Seven reports have so far been published (Wildy 1971; Fenner 1976; Matthews 1979, 1982; Francki et al. 1991; Murphy et al. 1995; Van Regenmortel et al. 2000a). The 7th ICTV Report published in 2000 lists three orders, 63 families, 240 genera, and 1 550 viral species.

An important change in the 7th Report (Van Regenmortel et al. 2000a) was that the criteria used for demarcating species within many genera were defined for the first time. In the 6th Report, more than 3 600 viral 'entities' were listed, without, in many cases, a clear indication of their status as species, strains, serotypes, or isolates. In the 7th Report, only 1 550 viral species were officially recognized as distinct taxonomic entities. The major changes in the classification scheme introduced in the 7th Report have been summarized by Fauquet and Mayo (2001). The 7th ICTV Report needs to be consulted to ascertain the current status of virus taxonomy. This information is also available on the ICTVnet (www.danforthcenter.org/ITAB/ICTVnet). Subsequent changes introduced up to July 2002 and approved by the ICTV are listed in Mayo (2002). The 8th ICTV Report is currently under preparation and is likely to be published in 2005.

The activities of the ICTV are publicized in the 'Virology Division News' section of *Archives of Virology*, which is the official journal of the Virology Division of IUMS (Mayo and Van Regenmortel 2000).

THE SPECIES ISSUE IN VIROLOGY

All classifications are conceptual constructions made up of classes (hence their name) and the categories used for building them are not found in nature but arise in human minds. The categories of species, genus, family, and order are abstract concepts which, like all abstractions, have no location in space and time. The categories should therefore not be confused with groups of real objects or organisms which obviously are located in space and time. The distinction is readily accepted in the case of genera, families, and orders, and virologists have no difficulty in regarding these categories as abstract constructions that they will never physically encounter in their handling of viruses. It is indeed impossible to centrifuge a virus family, i.e. a concept, or to visualize it in an electron microscope. It is, therefore, rather odd that in the case of the species category, the distinction tends to be blurred with the result that species are often considered to have a real spatiotemporal existence. Part of the problem lies in the fact that the term species has been given different meanings. In addition to referring to a class or category, which is an abstract concept, the term species is sometimes used to refer to a collection of concrete objects, or real organisms localized in space and time (Ghiselin 1997). On the other hand, when a species is viewed, correctly, as an abstract class, it is impossible for concrete individuals to be part of such a species since the part–whole relationship does not apply to entities of different logical type. The entities or organisms belonging to such a species can only take part in a relation known as class membership (Mahner and Bunge 1997). An organism can only be a **member** of the species and not a **part** of it because it is logically impossible for a concrete object to be part of an abstract entity, i.e. of an entity of different logical type

(Van Regenmortel 2003). It is of course impossible for a virus species to cause a disease since abstractions do not cause diseases. On the other hand, a concrete virus entity that causes a disease can be a member of an abstract virus species. Unfortunately, many authors are inclined to use shorthand, sloppy expressions and will write that the species *Mus musculus* has been inoculated with one or other virus species, instead of saying correctly that a mouse (a member of the species *Mus musculus*) has been inoculated with a member of a certain virus species (i.e. with particles of an isolate of a certain species).

Another difficulty arises because classes like genera and families are so-called universal or Aristotelian classes, i.e. classes defined in terms of properties that are collectively necessary and sufficient for membership in the class. A virus family, for instance, is a universal class that consists of members, all of which share a number of defining properties that allow unambiguous identification of any member. For instance, all members of the family *Herpesviridae* are enveloped viruses that contain an icosahedral particle and double-stranded DNA and it is possible to allocate a virus to this family by considering only a few morphological and chemical features. By contrast, a virus species is not a universal class because its members undergo continual evolutionary changes and always show considerable variability. In practice, this means that it is not possible to rely on a single discriminating property for differentiating between two species. It is for this reason that although the species category is the most fundamental one in any biological classification, it has been the most difficult one to apply in virus classification.

Species are fuzzy sets

The difficulty of defining species is not a problem restricted to virus classification but is prevalent in all biological classifications. It often comes as a surprise that more than a century after the publication of Darwin's *On the origin of species* there is no general agreement about what constitutes a plant, animal, or microbial species. As many as 22 different species concepts have been used in various fields in biology (Mayden 1997).

The traditional view of species is that they correspond to groups of similar organisms that can breed among themselves and produce fertile offspring. A classical definition of biological species states that 'species are groups of interbreeding natural populations that are reproductively isolated from other such species' (Mayr 1963). One problem with this definition is that it can only be applied to organisms that reproduce sexually; furthermore, it also does not take into account the phenomenon of interspecies hybridization which is very common in the plant kingdom. In order to make it applicable to asexual organisms for which the criterion of interbreeding breaks down, Mayr (1982) modified his definition to: 'a species is a reproductive community of populations, reproductively isolated from others, that occupies a specific niche in nature.' Another species concept is that of evolutionary species which has been defined as 'a single lineage of ancestor–descendant populations which maintains its identity from other such lineages and which has its own evolutionary tendencies and historical fate' (Wiley 1981). This concept emphasizes the historical dimension but does not provide any guidance on how far back in time a species can be traced. Life on earth is a biological and historical continuum and it is equally difficult to demarcate boundaries in time for identifying evolutionary species as it is to define clearcut breeding discontinuities in order to identify biological species. These difficulties led to the view that species are fuzzy sets with hazy boundaries and that it is not possible to draw sharp boundaries between them as is done with universal classes and classical sets. The use of fuzziness or vagueness for describing reality has a long history in Western thinking. Vagueness stems from the existence of a continuum with innumerable steps and is illustrated by the sorites paradox of the heap described by Greek philosophers. This paradox arises because it is impossible to say how many grains of sand can be removed from a heap before it stops being a heap. Clearly, the concept of a heap cannot be defined in a precise manner and it would be counterproductive to try to impose an artificial precision on such a term.

Fuzzy logic is a method that has been developed to handle concepts and entities that do not possess sharp boundaries (McNeill and Freiberger 1993). Fuzzy logic as a method for handling fuzzy sets accepts the inherent imprecision of terms and categories used in both ordinary language and in science. In ordinary language, a glass can be said to be full when it is only 95 or 98 percent full and the statement 100 percent full is rarely relevant. In classical logic, on the other hand, it will be maintained that a glass is necessarily either full or not full. In the real world of empirical and scientific observations this dichotomy is absent since fullness admits of degrees. Since fuzzy sets have no sharp boundaries, membership of a fuzzy set is not an all-or-nothing matter. This means that the two pillars of classical logic, the law of excluded middle (a swan is either white or nonwhite) and the law of noncontradiction (a swan cannot be both white and nonwhite) do not apply to fuzzy sets. Handling fuzzy sets falls outside the scope of classical, bivalent logic. When fuzziness is accepted as an unavoidable ingredient of the species concept, it becomes possible to describe species in terms of continuums devoid of artificial sharp edges (Van Regenmortel 1998). In a biological classification, it is often necessary to allocate an organism to a particular species purely as a matter of convenience and expediency rather than logical necessity. In a similar way, colors can be distinguished conceptually in spite of the continuous

nature of the spectrum of electromagnetic waves and mountain peaks can be identified and are given names in spite of the absence of sharp boundaries in geological rock formations (Van Regenmortel 2000a).

What is a virus species?

The question of what is a virus species is related to the general problem of deciding if one virus is the same as another. This in turn requires that an answer be given to the identity question: how different must two virus isolates be in order to be considered different types of virus rather than the same virus? Although mutants or pathogenic variants may be clearly distinguishable from the wild-type virus, virologists usually have no difficulty in recognizing them as being the same type of virus. This ability to pass judgment on the significance of the extent of difference observed between individual objects is a typically human faculty that in turn gives rise to our urge to classify and order the world around us. In biology, the hierarchical categories of family, genus, and species are used to classify organisms, the species class being the most difficult one to define. Since viruses are biological entities, albeit not living organisms, the ICTV has attempted to use the same categories for classifying viruses. Whereas the categories of family and genus were readily accepted by most virologists, it took many years before the species category gained acceptance by the virological community as a whole. As recounted in detail elsewhere (Van Regenmortel 1989), there was considerable opposition among plant virologists to the idea that the concept of species could be applied to viruses (Milne 1984; Harrison 1985). The unwillingness of some plant virologists to accept the species category was due to two erroneous assumptions on their part (Milne 1984). They assumed that the only legitimate species concept was that of biological species defined by gene pools and reproductive isolation, thereby ignoring the many other definitions of species some of which may have been applicable to entities such as viruses (Ghiselin 1997; Mayden 1997). They also assumed that the acceptance of virus species would inevitably lead to the latinization of virus names which they strongly opposed (Matthews 1983; Van Regenmortel 1989).

The battle against the use of the species category in virology was very much an argument over semantics. For many years some of the plant virologists who objected strongly to the term species had been engaged in a most successful enterprise of delineating separate plant viruses known as the *CMI/AAB Descriptions of Plant Viruses* (Matthews 1985). These *Descriptions* of more than 300 plant viruses were widely accepted as the standard demarcation of separate viruses. Instead of calling them separate species, however, the editors of the *Descriptions* preferred to call them 'viruses' where the inverted commas were meant to convey the message that these entities corresponded to a separate taxon and not merely to a particular viral strain or isolate. These 'viruses' really represented de facto species and plant virologists were in fact ahead of vertebrate virologists in delineating viral species, but without actually calling them species (for a review, see Van Regenmortel 1989).

The arguments against the use of the term species were also reinforced by the absence of an appropriate definition of the concept of virus species. In 1981, the ICTV had approved the following definition: 'A virus species is a concept that will normally be represented by a cluster of strains from a variety of sources, or a population of strains from a particular source, which have in common a set of correlating stable properties that separate the cluster from other clusters of strains' (Matthews 1982). Since this rather unhelpful definition did not explain what a strain was and did not indicate that viruses possess genes, Kingsbury (1985) suggested that it should be replaced by the following definition: 'A virus species is a population of viruses sharing a pool of genes that is normally maintained distinct from the gene pools of other viruses.' One difficulty with this definition is that many viruses reproduce entirely by clonal means and do not possess gene pools.

In order to emphasize the cohesive forces present in ancestral descendant clones that share a common biotic niche, the following definition was proposed in 1989: 'A virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche' (Van Regenmortel 1989). This is the definition which the ICTV endorsed in 1991 (Pringle 1991).

Virus species as polythetic classes

The concept of polythetic class was introduced in biology by Beckner (1959) who initially called this class polytypic to differentiate it from classical, universal classes defined by properties that are both necessary and sufficient for membership in the class. A polythetic class is characterized by a combination of properties, each of which might also occur outside the given class and could also be absent in a particular member of the class. Although the members of a polythetic class always have several properties in common, there is no single attribute absent in other classes which they all share (Figure 2). This means that no single property can be used as a defining property of a polythetic species on the basis that it is universally present in all the members of the species, and at the same time, always absent in the members of other species. It is for this reason that a single discriminating character, such as a certain percentage of genome sequence dissimilarity or a particular host reaction, cannot be used as a valid criterion for differentiating two virus species within the same genus. It is the inherent variability of the members of a species that prevents a single discriminating character from

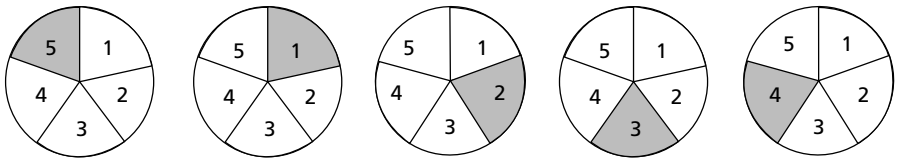

Figure 2 *Schematic representation of five members of a polythetic class characterized by five properties, 1–5. Each member possesses several of these properties, but no single property is present in all the members of the class. The missing property in each case is represented by the gray sector.*

being used for species differentiation (Van Regenmortel 2000a; 2003). It is always a combination of properties that must provide the justification for considering that two virus species are different.

The advantage of defining virus species as polythetic classes is that this makes it possible to accommodate individual viruses that lack one or other character that would normally be considered typical of the species. Polythetic classes are thus well-suited for dealing with biological entities like viruses which undergo continual evolutionary changes and show considerable variability.

Since there are mostly no sharp boundaries between different virus species, they are best treated as fuzzy sets (see section on Species are fuzzy sets). Species are thus very different from the other taxonomic categories used in virus classification, such as genera and families which can easily be defined in an unambiguous manner by a few morphological and chemical characteristics. The difficulties inherent in defining virus species are demonstrated by the fact that it was only in the 7th ICTV Report published in 2000 that the criteria used for differentiating many of the virus species were clearly stated for the first time.

Virus species as replicating lineages

The membership of a virus species varies over time and since all the members share descent from a common ancestor, they represent an evolving lineage. Since shared descent is a property that also links different species and genera, phylogeny is not a useful criterion for species demarcation. The same shortcoming applies to the evolutionary species concept since there are no clearcut criteria for deciding how far back in time a species can be traced (Wiley 1978; Lovtrup 1979). Virus species undergo continuous variation in time and transition from one species to another during evolution occurs within the continuity of gene duplication. As variations accumulate, a point will be reached where the importance of phenotypic and genotypic differences will lead an observer to conclude that he is dealing with a different virus species. Although increasing dissimilarity in genome sequence may provide some guidance, it must be stressed that there is no precise degree of genome difference which can be used as a cutoff point to differentiate between two species. The reason for this is that there is no direct quantitative relationship between the extent of genome sequence similarity and the similarity in biological or phenotypic characteristics of a virus. Since the biological properties of viruses are the ultimate reason why virologists engage in species demarcation, it would be unrealistic to differentiate between viral species only on the basis of genome properties. Unfortunately, there is at present an increasing tendency to want to rely only on genomic data for virus classification (Calisher et al. 1995; Zanotto et al. 1996). It should be borne in mind that classifying viral genomes is not the same as classifying viruses (Van Regenmortel et al. 1997) and that a viral nucleic acid sequence is not the same as a virus (Drebot et al. 2002). Genome comparisons cannot by themselves justify taxonomic placements that would disregard the biotic and phenotypic characteristics of viruses which remain the most important justification for developing a practical viral taxonomy.

Ecological niche occupancy

The ecological niche refers to the biotic properties of members of a virus species such as the host range, tissue tropism, and vector. The ecological niche does not only refer to a location in space but is a functional concept based on the relational properties of the virus (see Viruses should not be confused with virus particles or virions) which involves aspects such as host responses, pathogenesis, and virulence. The niche is not a property of the environment but a property of the virus related to its biotic habitat. There are, therefore, no vacant or empty niches but only unoccupied habitats or geographic spaces. In the absence of the virus, its ecological niche property is also absent and the notion of a vacant niche is thus meaningless (Colwell 1992). A niche provides the needs that must be met for the virus to replicate and to survive.

What is a type species?

Although the term 'type species' appears in the *International Code of Virus Classification and Nomenclature* (Mayo and Horzinek 1998), a precise definition of the concept has been proposed only recently: 'A Type Species is a species whose name is linked to the use of a particular genus name. The genus so typified will always contain the Type Species' (Mayo et al. 2002).

A type species is thus a nomenclatural or name-bearing type corresponding to a class which itself is included in a particular genus class. A type species, therefore, only typifies the use of the genus name and is not typical in the sense of possessing the greatest number of characteristics of the genus. Some confusion may arise if the concept of virus species as an abstract class is not clearly differentiated from that of the concrete infectious entity called a virus. A virus species may have as one its members a reference type which could for instance be a culture collection isolate that can be exchanged between laboratories and is useful for making comparisons with any new isolate. Such a reference type is actually a type strain and should not be confused with a type species, which being a species, is an abstraction and not a virus culture (Mayo et al. 2002).

The quasi-species misnomer

In recent years it has become fashionable to refer to RNA viruses as quasi-species populations (Smith et al. 1997). RNA viruses have genomes that replicate in the absence of repair mechanisms and they possess a mutation frequency per nucleotide site of 10^{-3}–10^{-5}. A clone of an RNA virus will, therefore, always generate many thousands of different genomes, all of which compete during replication of the clone (Holland et al. 1992). This population consists of a master sequence corresponding to the most fit genome sequence with respect to a given environment, together with a very large number of competing virus mutants. Such a population is often referred to as a quasi species. This is an unfortunate term since it implies that the virus corresponds to some sort of imperfect species, as opposed to a true or genuine species that would possess a single, invariant genome sequence (Domingo et al. 1995). Such an idealized virus species consisting of members that all have the same sequence of course does not exist (Van Regenmortel et al. 1997). The confusion arises because a chemical concept, i.e. that of a molecular species consisting of molecules that are all identical, is applied to a biological entity that is not defined by chemical homogeneity but by its inherent variability. Like all biological entities that possess the ability to reproduce themselves or to replicate, viruses are endowed with an intrinsic variability that results from the error-prone process of nucleic acid duplication.

The term quasi species was introduced by Manfred Eigen and his colleagues to describe self-replicating RNA molecules which because of mutation do not consist of a unique molecular species (Eigen 1993). The members of a chemical species are all identical molecules whereas the members of a virus species are not. The biological and taxonomic concept of virus species, therefore, cannot be reduced to that of molecular or chemical species since it would amount to the reductionist fallacy of attempting to reduce biology to chemistry. Taxonomic species are always quasi-species in the molecular sense and no additional clarification is provided by giving the label quasi species to viral species (Smith et al. 1997). It has been proposed that a 'virus quasi-species corresponds to a dynamic distribution of non-identical but closely related mutants and recombinant viral genomes subjected to a continuous process of genetic variation, competition and selection, and which act as a unit of selection' (Domingo 1999). However, such a definition reduces viruses to genome sequences. The term quasi species is, indeed, used appropriately for describing a population of genome sequences rather than a population of viruses since the implicit reference to a unique molecular species then applies to a chemical species consisting of a single nucleotide sequence.

Virus species demarcation

Although the acceptance of a definition of virus species by the virological community was an important step for establishing a virus classification based on traditional taxonomic categories, it should be stressed that such a definition did not solve the problem of demarcating individual virus species. Defining the virus species concept amounted to defining the category of species classes and it did not do away with the need to delineate individual virus species in the classification scheme.

Demarcating individual species is an attempt to introduce some order into the bewildering variety of viruses and this task requires the input of individuals with extensive experience and expertise with the viruses in a particular taxon (Van Regenmortel et al. 1997). This is the reason why the task of demarcating individual species was assigned to the ICTV Study Groups composed of virologists who possess in-depth knowledge of particular areas of virology. Only specialists are aware of the facts, issues, and nuances about viruses and their biotic interactions and of the importance of making certain distinctions, which may not be the same in all virus genera, for achieving a convenient and useful classification (Van Regenmortel et al. 1997).

In order to differentiate between individual species, it is necessary to rely on properties that are not present in all the members of a genus or family, since such properties obviously will not permit species demarcation. Characters such as virion morphology, genome organization, method of replication, and number and size of structural and non-structural proteins are properties that are shared by all the members of a genus or family and which, therefore, cannot be used for demarcating individual species within a genus. The properties that are useful for discriminating between individual virus species are characters that are not necessarily constant within the species and which can often change as a result of only few mutations. This situation is responsible for

much of the difficulty of demarcating species. Another difficulty, discussed in the section Species are fuzzy sets is that species are fuzzy sets, which means that there is in most cases no logical necessity in any particular species demarcation. Taxonomy at the level of species tends to be mostly a matter of opinion. Properties that are useful for demarcating species are the natural host range, cell and tissue tropism, pathogenicity and cytopathology, mode of transmission, certain physicochemical properties, antigenic properties, and genome sequence similarities (Van Regenmortel et al. 1997). All these characters are not equally important for demarcating species in different viral genera and families. This is often deemed to be unsatisfactory, although there is really no need to harmonize discriminating criteria across all species, genera, and families. A classification scheme has to answer the practical needs of people who deal with viruses and these needs are not the same in all areas of virology. From a human perspective, all the organisms infected by viruses are not equally relevant and it is to be expected that human pathogens or pathogens that infect animals and plants of economic importance will be studied more intensely than, for example, the viruses that infect the myriad species of insects. Fine distinctions based on relatively minor differences in host range, pathogenicity, or antigenicity may thus seem to be more relevant for viruses that are of particular interest to humans (Van Regenmortel and Mahy 2004).

Since virus species are polythetic, the ICTV Study Groups, in order to demarcate the 1 550 species that are listed in the 7th ICTV Report, had to rely on a combination of properties rather than on the presence or absence of a single key feature. Once a species has been established in this manner it is possible, however, to identify a virus isolate as a member of that species by considering only a few of the properties of the species. For instance, if a virus isolate reacts with a panel of monoclonal antibodies in the same way as an established member of a given species, the virus will be considered a member of that species. This apparent contradiction between the need for many characters to define a virus species and the fact that a single property may suffice to identify a member of a species disappears when it is realized that species definition and demarcation is a different endeavor from virus identification (Van Regenmortel 2003).

VIRUS IDENTIFICATION

There is a common misconception that the existence of a definition of the concept of virus species should make it an easy matter to decide if a particular virus isolate is a member of an established virus species or not. One reason for this misconception is the failure to appreciate that it is only the abstract concept of species, as a class of classes, that can be defined by explaining the meaning of the concept. Individual viruses like any other concrete entities that are located in space and time cannot be defined but can only be named (Kitts 1984; Van Regenmortel 1990) and identified by the use of so-called diagnostic properties (Ghiselin 1984). A definition only explains the meaning of a concept but it does not provide the means to decide which concrete entities are members of an abstract class. What is required is a set of characters and diagnostic properties that can be used for identifying individual members of a particular species. For different virus species, different types of properties may have to be used (Van Regenmortel et al. 1997).

The identification of a virus isolate is a comparative process based on a limited number of diagnostic properties which clarifies the extent of the relationship of the isolate with known members of an established species. Practical aspects of the virus identification process have been discussed by Murphy (1996). For unambiguous identification it is often convenient to compare new isolates with virus strains available in culture collections such as the American Type Culture Collection. These strains and reference types, which should not be confused with type species (see section on What is a type species?), are chosen and designated not by the ICTV but by international specialty groups, some of which operate under the auspices of the World Health Organization and other agencies. Levels of classification below the level of species, such as strain, serotype, and isolate, are not the remit of the ICTV, although such entities may be listed in ICTV Reports, admittedly without being defined (Drebot et al. 2002). A viral strain is a biological variant of a given virus that is recognizable because it possess some unique characteristics that remain stable under natural conditions. A viral serotype is a strain that is recognizable because it possess unique antigenic properties that remain constant under natural conditions. In the 7th ICTV Report, human polioviruses 1, 2, and 3 are considered serotypes of the species *Poliovirus* and they clearly constitute stable replicating lineages, a feature which allowed them to remain distinct over time (Drebot et al. 2002). The fact that these three serotypes do not cross-protect against each other is sufficient reason for epidemiologists to want to consider them as separate, clinically relevant entities. This important differentiation is clearly feasible even if the three serotypes are classified as members of the same virus species. In human and animal virology, individual viral serotypes are recognized only if they do not cross-protect against each other. In plant virology, the cross-protection criterion is not relevant and the label serotype is given to any antigenic variant that can be recognized as such. A viral isolate, on the other hand, is simply one particular virus culture that is being studied and it may correspond to a member of a species, a strain, or an entity of unknown taxonomic status.

Deciding whether viral isolates correspond to strains or serotypes of an established species or belong to separate species remains in many cases one of the most difficult challenges that virologists are faced with. The ICTV

Study Groups continue to address this issue by providing species demarcation criteria that can serve as guidelines for identifying which properties of viral isolates will be most useful for diagnostic purposes.

THE ICTV DATABASE (ICTVdB)

Although only about 1 600 virus species are currently recognized by the ICTV, it has been estimated that about 30 000 different viruses, strains, and subtypes are kept in specialized laboratories, reference centers, and culture collections. One of the aims of ICTV is to develop a universal virus database, the ICTVdB, which will store primary descriptive data of virus isolates formatted for the DELTA Computer System (DEscriptive Language for Taxonomy). The ICTVdB intends to be the main repository for descriptive information on viruses at the strain and isolate level and it will therefore be a valuable resource for virus researchers or anyone who needs information on currently known viruses (Büchen-Osmond et al. 2000). The ICTVdB uses a decimal numbering system similar to that used for enzymes (Büchen-Osmond and Dallwitz 1996). The database has been constructed using a descriptor list of several hundred characters which have been translated into single property statements which can be recognized by the search facilities of the database and can be used for virus identification. The ICTVdB also provides links with genome sequence and protein sequence databases (GenBank and SWISS-PROT).

Information on the ICTVdB is available from the US website www.ncbi.nlm.nih.gov/ICTVdb/ or the UK site www.ictvdb.iacr.ac.uk/

Information on individual viruses stored in the ICTVdB should in future be a useful tool for ICTV Study Groups when they need to make decisions regarding species demarcation and other taxonomic assignments.

NAMES AND TYPOGRAPHY OF VIRUS SPECIES

In the 6th ICTV report (Murphy et al. 1995), names of viral orders, families, subfamilies, and genera were written in italics with a capital initial letter. Following the 1998 revision of the International Code (Mayo and Horzinek 1998), the same typography was used for the names of virus species in the 7th Report. This typography provides a visible sign that species correspond to viral taxa, just like genera and families. For most viruses, the English common names of viruses became the species names and these were written in italics with the initial letter capitalized (Van Regenmortel 1999). This made it possible to differentiate virus species officially recognized by the ICTV from other viral entities such as tentative species, viral strains, and serotypes written in Roman characters. This new typography has met with some criticism (Bos 2000; Gibbs 2000) and corresponding rebuttals (Van Regenmortel 2000b; Van Regenmortel et al. 2000b) and is now generally applied in most scientific publications (Mahy 2001). The use of italicized English names for virus species reflects the emergence of English as the international language of scientific communication and is in line with the general dislike of virologists for Latin virus names (Van Regenmortel 2000b; 2003).

It should be emphasized that italicized virus species names are not meant to replace existing vernacular or common names of viruses written in Roman characters (Van Regenmortel and Fauquet 2002). The viruses studied by virologists are concrete, disease-causing entities and not abstract classes and they should be referred to by their common, non-italicized names. It is only the names of viral taxonomic classes that are written in italics, not the names of viruses (Drebot et al. 2000). In a scientific paper it will be necessary to refer only once, for instance in the Materials and Methods section, to the official, taxonomic species name, while in the remainder of the text reference will be made to the virus as a physical entity, denoted by its common name written in Roman characters (Van Regenmortel and Mahy 2004).

The claim that common virus names can be used in an abstract, taxonomic sense (Bos 2002) is based on the erroneous assumption that a virus is an abstraction rather than a concrete entity. A virus name is a sign or label that designates a real, concrete object located in space and time, and the word virus corresponds to what logicians call a general term which denotes any number of concrete objects or entities. The word 'virus' itself as a term referring to an infectious entity and the picture of a 'virion' should not be confused with the real objects to which they refer and which are the entities studied by virologists. The painter Magritte reminded us of that distinction in his well-known painting of a pipe that included the caption 'this is not a pipe.' A pipe is a general term denoting concrete objects and is no more an abstraction than a virus or a virus-infected plant (Van Regenmortel 2003). Only confusion results if a virus is considered to be an abstraction (Bos 2000; Van Regenmortel 2000b). Abstractions are concepts that are not located in space and time; examples are concepts like beauty, generosity, disease, and class (Mahner and Bunge 1997). Taxonomic classes are abstractions and the use of italics for the names of viral classes is a useful reminder of their abstract nature. Common names of viruses actually refer to concrete objects and not to abstract taxonomic categories, and this distinction is a crucial one when constructing a virus classification.

A POSSIBLE FUTURE BINOMIAL NOMENCLATURE FOR VIRUS SPECIES

For many years, some plant virologists have been using an unofficial binomial system for referring to virus species. In this system, the word 'virus' appearing at the

end of the current species name is replaced by the genus name, which also ends in 'virus;' *Tobacco mosaic virus* then becomes *Tobacco mosaic tobamovirus*, *Bluetongue virus* would become *Bluetongue orbivirus* and *Measles virus* would become *Measles morbillivirus*. The advantage of such as system is that inclusion of the genus name in the species name provides additional information about the properties of the viruses. To non-specialists, it would become immediately obvious that hepatitis A, B, and C viruses are very different entities belonging to separate genera if their species names would be *Hepatitis A hepatovirus*, *Hepatitis B orthohepadnavirus* and *Hepatitis C hepacivirus*. If such names became official names recognized by the ICTV, they should, of course, be written in italics, as they are in fact simply a contraction of the current species and genus names written in italics.

A binomial system for species names would have the additional advantage that there would then be a clear distinction between the species name written in italics (*Measles morbillivirus*) and the common non-italicized, virus name, measles virus. At present, the distinction between the name of the virus and that of the species relies in most cases only on typography (measles virus and *Measles virus*), which can lead to confusion (Van Regenmortel and Fauquet 2002).

The issue of whether nonlatinized binomial names should become the official species names of viruses has been hotly debated for many years (Bos 2000; Gibbs 2000; Van Regenmortel 2000b, 2001) and the ICTV has been criticized by some plant virologists for not making binomial names the official names of all virus species. However, the ICTV has moved cautiously since it was not clear whether a majority of virologists would be in favor of a binomial system that would lead to a change of all the current, official names of virus species. Efforts were made in 2002 to canvass the opinion of virologists regarding the acceptability of binomial names. The results of two ballots showed that a sizeable majority (80–85 percent) of the virologists (about 250) who expressed an opinion were in favor of a binomial system of species names (Mayo 2002; Van Regenmortel and Fauquet 2002; Van Regenmortel and Mahy 2004). This is the first time that the ICTV has obtained some indication about the way virologists feel about a particular taxonomic issue. Those who oppose a binomial system may still want to argue that the number of virologists who expressed an opinion is too small to justify a change in species names. Published taxonomic debates are usually conducted by a very small number of strongly opinionated individuals and the ICTV has always found it difficult to implement some sort of democratic decision-making since very few virologists bother to express their views on matters of taxonomy (Matthews 1983; Van Regenmortel 2000b; Van Regenmortel et al. 2000b). In the case of binomial species names there is now at least some indication on how the virological community thinks about the issue. At present, it is not clear whether the ICTV will change the International Code of Virus Classification and Nomenclature and will introduce new binomial names for all virus species.

The concept of the virus species	17		

INTRODUCTION

A formal taxonomy of viruses, known now as The Universal System of Virus Taxonomy, has developed from the operational need for a uniform system of nomenclature of viruses to facilitate the accurate identification and control of nonbacterial disease-producing agents. The concept of virus originated from the discovery that tobacco mosaic disease of plants could be transmitted by sap that had been rendered free of bacteria by passage through a Chamberland filter. Subsequently, the particulate nature of viruses was established by Loeffler who observed that foot-and-mouth disease of cattle was transmitted by a nonbacterial agent that could pass through Kieselguhr filters, but was retained by finer-grained Kitasato filters (see Witz 1998). Following the discovery of these viruses at the turn of the century, several other diseases were recognized as virus-associated. The physical nature of viruses remained unknown for several decades, however, and viruses were named and grouped according to their biological attributes, for example, pathogenicity, host range, tissue and organ specificity, transmission routes, etc. As knowledge of the chemical and physical properties of viruses accrued, it became apparent that the disease-producing potential of viruses was an unsound basis for virus classification. With the rapid expansion of virology from the 1950s onwards, the requirement for a uniform system of nomenclature became compelling. Several competing classification schemes were proposed based on a variety of criteria, but none gained wide acceptance. Systems of nomenclature at the extremes ranged from a rigid hierarchical system embracing subphyla, classes, orders, and families, based on an arbitrary set of characteristics (Lwoff et al. 1962), to a nonhierarchical system whereby any virus could be identified by a unique cryptogram defined by eight virus properties (Gibbs et al. 1966). To introduce order into this undertaking, an International Committee on Nomenclature of Viruses (ICNV) was established at the International Congress of Virology in Moscow in 1966. This committee was renamed the International Committee on Taxonomy of Viruses (ICTV) in 1973, and now operates under the auspices of the Virology Division of the International Union of Microbiological Societies (IUMS). The Universal System of Virus Taxonomy has been developed to its present state through a series of seven reports, the most recent of which was published in 2000 (Wildy 1971; Fenner 1976; Matthews 1979, 1982; Francki et al. 1991; Murphy et al. 1995; van Regenmortel et al. 2000). The classification presented in this chapter is a condensed version of the Universal System of Taxonomy (Pringle 1999), which was published in full as the Seventh Report of the ICTV in 2000 (van Regenmortel et al. 2000), and includes all revisions that have been approved by the ICTV up to the time of its plenary meeting in Paris in July 2002 (Mayo 2002). It is inherent in the design of the Universal Taxonomy that it can accommodate change in the nomenclature of viruses, as knowledge accrues, without obscuring previous usage. An Eighth Report is nearing completion and will be published under the title *Virus Taxonomy: VIIIth Report of the International Committee on Taxonomy of Viruses*, edited by C.M. Fauquet et al., London: Elsevier Academic Press. The overall structure of the higher level of the taxonomy remains largely unaltered, the principal

difference being that the number of designated virus species has almost doubled, and is likely to continue to increase exponentially in future years.

The ICTV operates through six subcommittees, which coordinate the work of approximately 50 study groups, with a total involvement of some 450 virologists representing all areas of virology. Five of these six subcommittees have responsibility for bacterial viruses, fungal viruses, plant viruses, invertebrate viruses, and vertebrate viruses, while the sixth is concerned with the development of an electronic virus database (the ICTVdB). An executive committee oversees the activities of the subcommittees and their study groups, and prepares all taxonomic proposals for ratification by the full membership of the ICTV, which comprises the executive committee, the life members, and the national members (nominated by countries supporting a national microbiological society). Normally a new taxonomic proposal should be directed to the chair of the appropriate study group, who becomes responsible for its progress through the evaluation procedure. An updated list of the names and addresses of study group chairs and the membership of the ICTV can be accessed at the ICTV website (www.ncbi.nlm.nih.gov/ICTV). Taxonomic proposals under consideration can also be viewed at the ICTV website on an interactive basis.

The system of taxonomy adopted by the ICTV is sufficiently flexible to withstand the stress of the continual discovery of new viruses from an ever-increasing diversity of host organisms. A hierarchy of five taxa, ranked as orders, families, subfamilies, genera, and species, has been developed. Taxonomic categories below the species level, such as subspecies, strains, variants, genotypes, etc., are excluded from the taxonomy and are defined at the discretion of working virologists. The concept and definition of the category of virus species is central to the structure of the taxonomy, and the nature of the virus species is discussed separately under The concept of the virus species. Artificially constructed hybrid viruses, genetically engineered and re-engineered viruses, mutants, recombinants, and reassortants are not included in the Universal Taxonomy; their status is a matter for consideration by interested specialist groups. Satellite viruses, satellite genomes, viroids, and prions are included, but not dealt with in detail in this chapter.

DEFINITION OF TAXA

The order

The highest taxon, the order, comprises a group of families that have certain features in common. Currently only three orders are recognized. It is anticipated that the number of orders will increase in step with refinement of the methods of characterization of viruses. Orders are designated by names with the suffix *-virales*. For example, the order embracing all the monopartite negative-sense single-stranded RNA viruses is the *Mononegavirales*.

The family

The taxon below the order is the family and 68 families are now recognized. Families consist of groups of genera exhibiting common properties not present in other genera, and they are identified by the ending *-viridae*, for example, *Herpesviridae*. In some instances subfamilies have been introduced to accommodate new knowledge regarding the relationships of genera within families. Subfamilies are indicated by the suffix *-virinae*, for example, *Alphaherpesvirinae*. In general, however, the policy is to avoid subdivision of primary taxa, except for reasons of expediency. The family is the bedrock of the universal taxonomy and most have been reinforced rather than undermined by the accumulation of knowledge. The members of the same family have similar morphology, genome organization, and replication strategy. However, since virology has no fossil record to fall back on, proof of common phylogeny is not a defining property. Of the 68 virus families currently recognized, only 28 (38 percent) contain viruses with vertebrate hosts.

The genus

Virus genera are assemblages of species of viruses that share common properties that distinguish them from the members of other genera. Genera are designated by the suffix *-virus*, for example, *Simplexvirus*. Currently 250 genera have been designated, 222 of which have been assigned to families. The remaining 28 genera, mostly positive-sense single-stranded RNA viruses of plants, are referred to as unassigned or 'floating' genera. There are 99 genera of viruses infecting vertebrates, four of which remain 'unassigned.' The genera occupy the most stable level of the hierarchy and establish the point of departure from which other taxa are defined. It is inherent in the taxonomy at its present stage of development that there is a lack of equivalence in different branches, and the criteria used for definition of genera differ from family to family. Evidence of common phylogeny is a desirable but not an exclusive criterion for definition of a genus. The horizontal transfer of genetic information during virus evolution and the occasional incorporation of host-derived genes can rapidly obscure or mimic phylogenetic relationship. It is implicit in the designation of a genus, however, that its constituent species will not exhibit conflicting phylogenetic relationships.

The species

The species is the most important category in any system of biological taxonomy. The concept of species in

clonally related organisms is discussed under The concept of the virus species. The definition of virus species finally adopted by the ICTV is the one formulated by van Regenmortel (1990). This definition states that: 'A virus species is defined as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche.' A polythetic class is a class that is defined by more than one property, and no single property is necessary or sufficient to confer membership. The adjectival phrase 'ecological niche' refers to the total environment as distinct from its restrictive usage in contemporary environmental philosophies. The principal advantage of the van Regenmortel definition is that it takes account of the inherent variability of viruses and is not reliant on a single diagnostic characteristic. This definition is sufficiently elastic to accommodate the differing perceptions of virus species by virologists working in different fields of virology. One of the most difficult tasks facing virus taxonomists currently is to establish some uniformity in the nature of the phenotypic properties employed in the definition of species (van Regenmortel et al. 1997). The seventh report of the ICTV (van Regenmortel et al. 2000) should be consulted for detailed information concerning the criteria used for species designation in each family or floating genus.

The International Code of Virus Classification and Nomenclature

The naming of species has been codified (see Mayo and Horzinek 1998). A species name must be unambiguous and should consist of as few words as practicable, for example, *Human herpesvirus 1*. It must not consist solely of a host name with the word virus appended. A recent change in practice approved by the ICTV is that, in common with other biological taxonomies, virus species names will be rendered in italics with the initial letter capitalized. Tentative species, i.e. those with unconfirmed taxonomic status and awaiting approval are not italicized but do have the initial letter capitalized. Each species is also identifiable by a unique acronym (for example, see Fauquet and Martelli 1995; Fauquet and Pringle 1999a, b, 2000), which can be used unitalicized in text subsequent to the first mention of the species name, for example, ASFV is the approved acronym for *African swine fever virus*.

In future, all taxonomic categories from orders down to species should be rendered in italics with the initial letter capitalized. The name of the taxon should precede its actual name, for example, the genus *Simplexvirus*, rather than the *Simplexvirus* genus. This is the convention in the formal identification of a taxon, for example, in designation of the species *Tobacco mosaic virus*. In other circumstances, such as when used in an adjectival form, italicization and capitalization of the initial letter are not required; e.g. in the adjectival statement, the tobacco mosaic virus polymerase.

The use of vernacular nomenclature can be a source of ambiguity where a common root name is employed in designation of both family and genus. A pertinent example is the confusion generated by the use of the vernacular term 'paramyxovirus.' This is ambiguous because the vernacular term could refer either to viruses belonging to the genus *Paramyxovirus,* or to constituent members of the family *Paramyxoviridae*. This usage lacks precision because the family *Paramyxoviridae* comprises five uniquely named genera. To deal with this problem the Paramyxovirus Study Group of the ICTV recently decided that the genus *Paramyxovirus* should be renamed the genus *Respirovirus*, notwithstanding the familiarity and historical associations of the original name. Although the International Code of Virus Classification and Nomenclature (see Mayo and Horzinek 1998) states that existing names should be retained wherever feasible, priority is not a factor that is given precedence. To increase precision and to avoid ambiguity it is the intention in the longer term to eliminate all vernacular names from the Universal Taxonomy and to replace them with international names, for example, the species formerly designated as lambda phage is now designated the species *Enterobacteria phage λ*.

The International Code also requires that the names of taxa should be easy to use, euphonious, and easy to remember. No person's name should be used in designation of a new taxon. Nor should subscripts, superscripts, hyphens, oblique bars, and Greek letters be used in the designation of a new taxon, notwithstanding the fact that examples of these remain in the existing taxonomy. Sigla may be accepted as names of taxa, provided that their meaning is obvious to the members of the relevant study group and to general virologists. For example, the name of the genus *Reovirus* is a siglum compounded from 'r' for 'respiratory', 'e' for 'enteric', and 'o' for 'orphan'.

THE UNIVERSAL SYSTEM OF VIRUS TAXONOMY

Strategy of the viral genome

The order of presentation of taxa adopted by the ICTV is based on the four criteria that define the strategy of the viral genome (see The genetics of vertebrate viruses). The virus taxa are grouped according to (1) the nature of the viral genome; (2) the strandedness of the nucleic acid; (3) the facility for reverse transcription; and (4) the polarity of the genome. There are seven categories: single-stranded DNA viruses (Table 1), double-stranded DNA viruses (Table 2), reverse-transcribing viruses (Table 3), double-stranded RNA viruses (Table 4), negative-sense single-stranded RNA viruses (Table 5), positive-sense single-stranded

Table 1 *The taxonomy of single-stranded DNA viruses*

Order	Family [Subfamily]	Genus	Type species
–	*Inoviridae*	*Inovirus*	*Enterobacteria phage M13*
		Plectrovirus	*Acholeplasma phage MV-L51*
–	*Microviridae*	*Microvirus*	*Enterobacteria phage ϕX174*

Vertebrate virus taxa are indicated by absence of shading.
The dashes signify 'unassigned'.

RNA viruses (Table 6), and unconventional agents, comprising naked RNA viruses, viroids, and subviral agents (Table 7). The order of presentation does not imply hierarchical or phylogenetic relationship. In each table the viruses that infect vertebrates are indicated by the absence of shading. It will be obvious that no single strategy is typical of vertebrate viruses. The only unique strategy is exhibited by the wasp-infecting viruses of the family *Polydnaviridae*, which are the only viruses to possess segmented double-stranded DNA genomes. Otherwise segmentation is absent in DNA-containing viruses, although not uncommon among RNA-containing viruses, particularly those infecting plants. Segmentation of the genome may contribute to control of gene expression, but the consequences are different in the case of animal and plant viruses. The different segments of the genome of viruses infecting plants are encapsidated separately, possibly as an adaptation to movement within the host, and an infectious unit is a complement of particles. As far as is known in viruses infecting vertebrates the full complement of segments is encapsidated in each infectious particle.

The viruses infecting bacteria are predominantly DNA viruses, whereas the viruses infecting plants are either RNA viruses, viruses with a reverse-transcription stage in their multiplication cycle, or single-stranded DNA viruses. The viruses infecting fungi, invertebrates, and vertebrates may have either RNA or DNA genomes, and reverse-transcribing viruses infect all types of hosts except bacteria. The viruses of vertebrates and plants may also infect and multiply in invertebrates, but so far no virus is known that can infect all three types of host, and no vertebrate virus can multiply in plant hosts and vice versa.

The single-stranded DNA viruses

There are six families and one unassigned genus of viruses with single-stranded DNA genomes (Table 1). Viruses of two of the families and the unassigned genus infect vertebrates, and the remaining families embrace viruses found in bacteria, mycoplasmae, plants, and invertebrates.

THE FAMILY *CIRCOVIRIDAE*

The family *Circoviridae* comprises two genera, *Circovirus* and *Gyrovirus*, the type species of which are *Porcine circovirus 1* and *Chicken anemia virus*, respectively. The name of the family derives from the circular form of the approximately 2 kb genome. The vertebrate circoviruses resemble the plant nanoviruses, which have similar particle architecture and circular single-stranded DNA genomes. Indeed, the nanoviruses were initially classified as members of the family *Circoviridae* before achieving separate family status. *Porcine circovirus 1*, the type species of the genus *Circovirus*, resembles plant and bacterial viruses of the families *Geminiviridae* and *Microviridae* respectively, in terms of nucleic acid and protein homologies related to rolling circle DNA replication (Meehan et al. 1997).

The name *Anellovirus* has been proposed for an unassigned genus to include the recently discovered 'TT virus' and 'TT virus-like mini virus', which contain circular single-stranded DNA genomes of about 3.8 and 2.9 kb respectively. Despite their delayed recognition, these viruses are globally distributed in human and some nonhuman populations and may prove to be the most abundant of all viruses. The anelloviruses share similarities with the circoviruses regarding genome organization and expression, but all isolates possess negative sense genomes like chicken anemia virus (the sole member of the genus *Gyrovirus*) in contrast to the ambisense genomes of the circoviruses belonging to the genus *Circovirus*. The anelloviruses are unusual among DNA viruses in displaying extreme genetic heterogeneity.

THE FAMILY *PARVOVIRIDAE*

The family *Parvoviridae* comprises two subfamilies, the *Parvovirinae* comprising three genera of viruses infecting vertebrates and the *Densovirinae* comprising three genera of viruses infecting invertebrates. Viruses of both subfamilies possess linear single-stranded DNA genomes of 4–6 kb, unlike the other families of single-stranded DNA viruses where the DNA is circularized. The polarity of the single-stranded DNA encapsidated in virions varies according to species. *Murine minute virus* (genus *Parvovirus*) preferentially incorporates negative strands, whereas *Adeno-associated virus* (genus *Dependovirus*) incorporates strands of either polarity in quasi-equivalent amounts. The principal human pathogen in the single-stranded DNA virus category is *B19 virus*, which is classified as the type species of the third vertebrate-infecting genus, the genus *Erythrovirus*.

A feature distinguishing some viruses of the genus *Densovirus* from the vertebrate parvoviruses is encoding of the replicative function gene (REP) and the capsid protein gene (CP) on complementary strands. The processing of capsid proteins from the CP ORF involves splicing, which is mediated by an alternative splice donor in the case of viruses belonging to the genus *Parvovirus*, and an alternative splice acceptor in the case of viruses belonging to the genus *Densovirus*. Phylogenetic analyses support the formal taxonomy of the *Parvoviridae* (see *Virus Taxonomy, the Seventh Report of the ICTV*, van Regenmortel et al. 2000).

The double-stranded DNA viruses

There are 20 families and three unassigned genera of viruses with double-stranded DNA genomes (Table 2). Nine of the families and one of the unassigned genera contain viruses infecting bacteria, archaea or mycoplasmae, one family contains viruses infecting algae, four families contain viruses infecting invertebrates, and four families and one unassigned genus contain viruses infecting vertebrates. Two other families contain viruses with either vertebrate or invertebrate hosts. The unassigned fungal virus genus *Rhizidiovirus* was previously associated with the adenoviruses. There are no viruses infecting plants in this category.

The three families of bacterial viruses characterized by possession of complex contractile (*Myoviridae*) or noncontractile (*Siphoviridae* and *Podoviridae*) tail structures include 96 percent of the more than 4 500 bacterial viruses described in the literature. These three families are now grouped together as the order *Caudovirales* (Maniloff and Ackermann 1998). The species classified in these families infect hosts on most branches of the bacterial phylogenetic tree, and two of the three families include species infecting *Bacteria* and species infecting *Archaea*, suggesting that tailed viruses originated before the divergence of these hosts. The rationale for establishment of the order *Caudovirales* differs from that for the two orders of vertebrate viruses, *Mononegavirales* and *Nidovirale*s (see The negative-sense single-stranded RNA viruses and The positive-sense single-stranded RNA viruses), where there is evidence of common phylogeny and genome organization. Evidence of common phylogeny of the constituent members of the order *Caudovirales* cannot be expected on account of the time scale of evolution, the enormous population sizes, and the ecological diversity of the tailed bacterial viruses. The occurrence of horizontal gene transfer is another complicating factor. The criteria for creation of the order *Caudovirales* are the following: a highly conserved complex morphology; a common replication pattern, involving injection of DNA, formation of concatamers and cleavage to unit length progeny genomes; the insertion of DNA into preformed proheads fabricated on scaffolding proteins; and the release of the tailed particle by virally encoded lytic enzymes. This example illustrates that a logical and useful taxonomy of viruses can be constructed in the absence of knowledge of phylogenetic relationships.

THE FAMILY *POXVIRIDAE*

The family *Poxviridae* comprises species of virus infecting either vertebrate or invertebrate hosts. The members of the family are distinguished from the other double-stranded DNA viruses by their cytoplasmic site of multiplication. The genome is a single, linear molecule of covalently closed double-stranded DNA, 139–375 kbp in size. The subfamily *Chordopoxvirinae* consists of eight genera of viruses infecting vertebrates generally with restricted host ranges. The subfamily *Entompoxvirinae* embraces three genera of viruses infecting distinct insect hosts. The two subfamilies are also distinguished by a different linear arrangement of core genes. Phylogenetic analyses of poxvirus DNA polymerases, NTPases, thymidine kinases, and DNA uracyl glycosulases support the formal taxonomy in

Table 2. The major human pathogen, the species *Variola virus*, no longer exists in nature.

THE FAMILY *IRIDOVIRIDAE*

The family *Iridoviridae* comprises large enveloped icosahedral viruses with linear double-stranded DNA genomes of 140–300 kbp. Two of the four genera in the family are viruses with vertebrate hosts; that is, the genus *Ranavirus*, infecting amphibians, and the genus *Lymphocystivirus* infecting fish. The DNA of the vertebrate viruses is highly methylated, whereas the DNA of the invertebrate viruses is not. The vertebrate viruses possess an additional outer envelope derived by budding through the plasma membrane, which may also be present in invertebrate viruses grown in tissue culture, but this is not essential for infectivity. Phylogenetic analysis of major capsid protein sequences confirms the formal taxonomy, which is based on a variety of phenotypic properties.

The major capsid protein exhibits detectable amino acid sequence homology with the corresponding proteins of both *Paramecium bursaria Chlorella virus 1* of the family *Phycodnaviridae* and *African swine fever virus* of the family *Asfarviridae*. There are no recognized human pathogens in the famly *Iridoviridae.*

THE FAMILY *ASFARVIRIDAE*

The family *Asfarviridae* contains a single genus *Asfivirus*. The taxonomic position of the species *African swine fever virus* has been problematic in view of the distant homology with iridoviruses referred to above. Furthermore, there is resemblance to the *Poxviridae* in the intricate morphology, genome structure, and replication pattern of *African swine fever virus*. Originally this species was listed as a member of the family *Iridoviridae,* then later designated as the solitary member of an unassigned and unnamed genus. In the revised taxonomy of the seventh report it has been elevated to the status of type species of the genus *Asfivirus* of the family *Asfarviridae*. The name of the family is a siglum compounded from the phrase African swine fever and related viruses.

THE FAMILY *HERPESVIRIDAE*

The family *Herpesviridae* was one of the first taxonomic groups to be defined on the basis of virion properties rather than by disease association (Andrewes 1954). It now comprises three subfamilies and an unassigned genus. The order of the genes is largely conserved within subfamilies, but extensive gene rearrangement is observed between subfamilies. Each of the three subfamilies contains two or more genera, with important human pathogens in each subfamily. Related herpesviruses are classified as distinct species on the basis of quantifiable sequence differences across the whole genome and possession of distinct phenotypes with respect to host, epidemiology, or pathogenesis. For example the two serotypes of herpes simplex virus are now designated as the species *Human herpesvirus 1* and *Human herpesvirus 2* because these viruses exhibit sequence differences across the genome and infect different tissues with distinctive epidemiological consequences. The ability of these two species to undergo recombination in cultured cells is not considered relevant since no natural recombinants have been isolated despite the apparent parallel evolution of these viruses over millions of years.

The formal taxonomy of three subfamilies derived initially on the basis of phenotypic properties has been substantiated by phylogenetic analyses of eight

well-conserved genes. The viral phylogenies fit well with the host phylogenies derived from the fossil record. On the assumption of the existence of a constant molecular clock and cospeciation of virus and host, the divergence of the three subfamilies is estimated to have occurred 180–220 million years ago. Major sublineages discernible within each subfamily were probably established before the radiation of the *Mammalia* 60 to 80 million years ago, with speculation within these sublineages occurring subsequently (McGeoch et al. 1995).

The fish herpesviruses are anomalous and have been consigned temporarily to the unassigned genus *Ictalurivirus*. The species *Ictalurid herpesvirus 1* (which includes channel catfish virus) is classified as a herpesvirus on the basis of virion morphology, and indeed this virus was instrumental initially in deriving the structure of the mammalian alphaherpesvirus genome. However, nucleotide sequence analysis has revealed no specific relationship with mammalian herpesviruses at the amino acid sequence level, other than with respect to ubiquitous enzymes not unique to mammalian herpesviruses (Davison 1998). Consequently the fish and mammalian herpesviruses may have arisen independently and may have acquired similar morphologies by convergent evolution. Alternatively they may have evolved by divergence from a common ancestral herpesvirus and their phylogenetic relationship has been obscured by 400 million years of progressive covariation with their hosts. These findings illustrate again that taxonomy cannot be reduced solely to the classification of viruses by extent of sequence homology. It has been suggested recently that two additional families should be created: one to accommodate the fish and amphibian herpesviruses and the other to embrace some recently discovered herpesviruses from molluscs. These viruses exhibit common structural and physical organization but appear to have separate evolutionary histories from the avian and mammalian herpesviruses. It was further suggested that to resolve the taxonomic difficulties the three families should together constitute a new virus order, the *Herpesvirales* (Davison 2002).

THE FAMILIES *POLYOMAVIRIDAE* AND *PAPILLOMAVIRIDAE*

As a result of continuing molecular and genetic characterization of the small oncogenic DNA viruses, the family *Papovaviridae* has disappeared to be replaced by two new families, the *Polyomaviridae* and the *Papillomaviridae*. Both families include human pathogens. *Simian virus 40* now becomes the type species of the single genus *Polyomavirus* of the family *Polyomaviridae*, and *Cottontail rabbit papilloma virus* becomes the type species of the single genus *Papillomavirus* of the family *Papillomaviridae*. This situation illustrates an unresolved problem in virus taxonomy. The assignment of taxonomic levels is peculiar to each group of viruses, and as yet there are no rules or criteria for achieving parallelism or equivalence between different taxonomic lineages. These two families of small oncogenic DNA viruses may be the next candidates for inclusion in an order.

THE FAMILY *ADENOVIRIDAE*

The taxonomy of the family *Adenoviridae* has been revised as a result of synthesis of the extensive literature on the molecular and genetic properties of these viruses. The serotypes of the traditional classification of adenoviruses have now been grouped into species. Species are designated on the basis of several properties in accordance with the van Regenmortel definition. For example, lack of cross-neutralization, phylogenetic difference exceeding 10 percent, etc. The criteria are flexible so that where phylogenetic distance is <1 percent, additional criteria may be used, such as ability to recombine, degree of oncogencity, GC content, etc. The type species of the genus *Mastadenovirus* is now designated *Human adenovirus C*, which includes human adenovirus types 1, 2, 5, and 6, bovine adenovirus type 9, and simian adenovirus types 13 and 26. As a consequence of this revision the diversity of mammalian adenoviruses has been reduced to about 20 species.

The avian adenoviruses are serologically distinct from the mammalian adenoviruses and are included in the genus *Aviadenovirus*. The type species is *Fowl adenovirus A*. The avian adenoviruses lack the genes of mammalian adenoviruses that encode proteins V and IX, and also lack homologues of early regions E1 and E3. The avian adenoviruses have been grouped into five species in the same manner as the mammalian adenoviruses.

Since publication of the seventh report, two new genera have been added to the *Adenoviridae* as a result of characterization of adenoviruses from nonhuman hosts. The genus *Siadenovirus* includes only two species: a virus isolated from a leopard frog and an avian virus distinguishable antigenically and genetically from the other avian adenoviruses. The genus *Atadenovirus* embraces a larger group of adenoviruses originating from several different hosts, and which includes several serotypes of bovine adenoviruses and adenoviruses from a wide range of reptiles.

The reverse-transcribing viruses

There are five families of viruses that have a reverse transcription stage in their replication cycle (Table 3). Reverse transcribing viruses have been isolated from fungi, plants, invertebrates, and vertebrates, but not from bacteria. The families differ with respect to the stage of the replication cycle sequestered in the extracellular particle. Consequently some viruses encapsidate DNA in the virion, whereas others encapsidate RNA. Remarkably all of the known double-stranded DNA-

Table 3 *The taxonomy of reverse-transcribing viruses*

Order	Family	Genus	Type species
–	*Pseudoviridae*	*Pseudovirus*	*Saccharomyces cerevisiae Ty1 virus*
		Hemivirus	*Drosophila melanogaster copia virus*
–	*Metaviridae*	*Metavirus*	*Saccharomyces cerevisiae Ty3 virus*
		Errantivirus	*Drosophila melanogaster gypsy virus*
–	*Hepadnaviridae*	*Orthohepadnavirus*	*Hepatitis B virus*
		Avihepadnavirus	*Duck hepatitis B virus*
–	*Caulimoviridae*	*Badnavirus*	*Commelina yellow mottle virus*
		Caulimovirus	*Cauliflower mosaic virus*

		Betaretrovirus	*Mouse mammary tumour virus*
		Gammaretrovirus	*Murine leukemia virus*
		Deltaretrovirus	*Bovine leukemia virus*
		Epsilonretrovirus	*Walleye dermal sarcoma virus*
		Lentivirus	*Human immunodeficiency virus 1*
	[*Spumaretrovirinae*]	*Spumavirus*	*Simian foamy virus*

Vertebrate virus taxa are indicated by absence of shading.
The dashes signify 'unassigned'.

containing viruses of plants replicate via reverse transcription and have been grouped into the single family *Caulimoviridae.* Of the other four families, the *Hepadnaviridae* and the *Retroviridae* comprise viruses infecting vertebrate hosts only, and the *Metaviridae* and the *Pseudoviridae* contain viruses infecting either fungal or invertebrate hosts, according to genus.

THE FAMILY *RETROVIRIDAE*

The taxonomy of the retroviruses has been simplified in the latest revision, and there are now seven genera designated as *Alpharetrovirus*, *Betaretrovirus*, *Gammaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, *Lentivirus,* and *Spumavirus*. The genus *Alpharetrovirus* comprises the viruses previously designated as Avian type C retroviruses, and the genus *Betaretrovirus* embraces the viruses previously classified as the Mammalian type B retroviruses and the type D retroviruses. The genus *Gammaretrovirus* replaces the former Mammalian type C retroviruses and in addition includes the reptilian type C oncoviruses and the *Reticuloendotheliosis viruses*. The genus *Deltaretrovirus* includes the former 'BLV-HTLV-like retroviruses.' A new genus, *Epsilonretrovirus*, has been introduced to accommodate several complex retroviruses isolated from fish. The genus names *Lentivirus* and *Spumavirus* have been retained from earlier classifications on the principle inherent in the nomenclature code that 'existing names of taxa should be retained wherever feasible.'

The family *Retroviridae* embraces vertebrate viruses with genomes consisting of a dimer of linear positive-sense single-stranded RNA. The monomers range in size from 7 to 12.8 kb and are held together by hydrogen bonding. Purified virion RNA is not infectious. Each monomer is polyadenylated at the 3′ end, and has a type 1 cap structure at the 5′ end. A specific tRNA is base-paired to a primer-binding site near the 5′ end. Infectious virus has four major genes in the order 5′–gag–pro–pol–env-3′. The *pro* gene encodes a specific protease, and the *pol* gene encodes the reverse transcriptase and an integrase. Additional cell-derived genes may be present as additions or substitutions in retroviruses classified in the genera *Alpharetrovirus*, *Betaretrovirus*, and *Gammaretrovirus*, with important pathogenic consequences. Viruses may become helper-dependent as a result of gene substitution. Retroviruses classified in the genera *Deltaretrovirus*, *Epsilonretrovirus*, *Lentivirus*, and *Spumavirus* contain genes encoding additional nonstructural proteins, which play a role in control of gene expression and viral replication. Integration into cellular DNA is an obligatory stage in the multiplication cycle. As a consequence retroviruses exist as both exogenous infectious agents of vertebrates, and as endogenous proviruses inherited as Mendelian genes as a result of infection of germ line cells. The latter are not part of the universal taxonomy at present. Phylogenetic analysis of the pol genes of retroviruses produces trees consistent with the formal taxonomy (see *Virus Taxonomy, the Seventh Report of the ICTV*, van Regenmortel et al. 2000).

THE FAMILY *HEPADNAVIRIDAE*

The family *Hepadnaviridae* contains two genera of DNA viruses. The genome of hepadnaviruses consists of a

single molecule of circular DNA, 3.0–3.3 kb in size, which is not covalently closed. The DNA may be partially single-stranded in the virion, the extent of this differing in the two genera. The reverse-transcription stage in the replication cycle occurs in the cytoplasm and consequently integration into cellular DNA is not an obligatory or usual part of the cycle. *Hepatitis B virus* is the type species of the genus *Orthohepadnavirus* and *Duck hepatitis B virus* is the type species of the genus *Avihepadnavirus*. Host range is the primary determinant of assignment of species to genus.

THE FAMILIES *CAULIMOVIRIDAE*, *METAVIRIDAE*, AND *PSEUDOVIRIDAE*, THE NONVERTEBRATE FAMILIES OF REVERSE-TRANSCRIBING VIRUSES

The family *Caulimoviridae* contains five genera of plant-infecting DNA viruses. The genome is a single molecule of circular DNA, 7.2–8.1 kbp in size. The genome contains between two and seven ORFs, depending on the genus. The organization of the genome is one of the principal distinguishing features of the individual genera. The functions of the virus-encoded proteins common to all genera are the following: the capsid protein gene, an aspartate protease, a reverse transcriptase, and ribonuclease H. Additional gene functions relate to movement in the plant host and vector transmissibility. The replication cycle is episomal and does not involve an integration phase.

The family *Metaviridae* includes species of retrotransposons infecting yeast (the genus *Metavirus*) or invertebrates (the genus *Errantivirus*), and the family *Pseudoviridae* includes the retroelements known as LTR-retrotransposons infecting yeast (the genus *Pseudovirus*) and invertebrates (the genus *Hemivirus*).

The double-stranded RNA viruses

Double-stranded RNA viruses have been isolated from bacteria, fungi, plants, invertebrates, and vertebrates (Table 4). These viruses are classified into six families and one unassigned genus. The double-stranded RNA viruses are predominantly segmented genome viruses. Four of the six families and the unassigned genus contain viruses with segmented genomes. Two of the families, the *Reoviridae* and the *Birnaviridae*, contain viruses infecting vertebrate hosts, although not exclusively.

THE FAMILY *REOVIRIDAE*

The family *Reoviridae* comprises ten genera: six (*Aquareovirus*, *Coltivirus*, *Orbivirus*, *Orthoreovirus, Rotavirus*, and *Seadornavirus*) contain vertebrate-infecting viruses, three (*Fijivirus*, *Phytoreovirus*, and *Oryzavirus*) plant-

Table 4 *The taxonomy of double-stranded RNA viruses*

The dashes signify 'unassigned.'

infecting viruses, and one (*Cypovirus*) invertebrate-infecting viruses. Reoviruses contain 10, 11, or 12 segments, depending on the genus, of linear double-stranded RNA. The cypoviruses share a property in common with the DNA-containing baculoviruses. Namely, possession of a gene encoding a polyhedrin protein which provides a protective matrix to enhance the survival of virus released into the environment after excretion from the gut or on death of the host.

In this family the prime determinant for classification of viruses into species is the Darwinian criterion of ability to exchange (reassort) genome segments. However, such information is rarely available and the genetic compatibility of isolates is estimated indirectly from serological, physical, and sequence data. The electropheretic migration patterns of the double-stranded RNA genome segments isolates (the electropherotype) may also be employed on account of their high resolution and reproducibility, particularly in the case of rotaviruses many of which cannot be propagated in vitro.

THE FAMILY *BIRNAVIRIDAE*

The family *Birnaviridae* comprises three genera of viruses with bisegmented linear double-stranded RNA genomes. The larger genome segment is variable around 3 kbp in size, and the smaller more homogeneous around 2.7 kbp. There are minor differences in the processing of the viral genes between genera, and the taxonomy is based on serology, host range, and pathology. Two of the three genera contain vertebrate-infecting viruses: species of the genus *Aquabirnavirus* are major pathogens of salmonid fish, and *Infectious bursal disease virus*, the type species of the genus *Avibirnavirus*, is an important pathogen in the poultry industry. The natural host of *Drosophila X virus*, the type species of the genus *Entomobirnavirus*, is probably *Culicoides* spp., with infection rendering the host sensitive to CO_2.

THE NONVERTEBRATE FAMILIES OF DOUBLE-STRANDED RNA VIRUSES

The bacterial viruses of the family *Cystoviridae* have tripartite genomes of some 13 kbp in total. The fungal and plant viruses of the famly *Partitiviridae* have bipartite genomes of 2.8–6.0 kbp total. The unassigned genus *Varicosavirus* also has a bipartite linear genome of 13.5 kbp total. The *Totiviridae* and *Hypoviridae*, on the other hand, have nonsegmented linear double-stranded RNA genomes of some 4.6–7 kbp and 9–13 kbp total, respectively.

The negative-sense single-stranded RNA viruses

Vertebrate-infecting viruses are classified in all seven families of negative-sense single-stranded RNA viruses (Table 5). Plant viruses are included in two of the seven families and are the sole representatives of the two unassigned genera, *Ophiovirus* and *Tenuivirus*. *Deltavirus* is formally included with the negative-sense RNA viruses as an unassigned genus, although the single species *Hepatitis D virus* exists only as a satellite of the species *Hepatitis B virus* (family *Hepadnaviridae*). At this time no negative-sense single-stranded RNA virus has been isolated from bacteria, fungi, or protozoa.

THE MONOPARTITE NEGATIVE-SENSE GENOME VIRUSES – THE ORDER *MONONEGAVIRALES*; COMPRISING THE FAMILIES *BORNAVIRIDAE*, *FILOVIRIDAE*, *PARAMYXOVIRIDAE*, AND *RHABDOVIRIDAE*

The first order in viral taxonomy was created to embrace the three families, *Filoviridae*, *Paramyxoviridae*, and *Rhabdoviridae*, on the basis of similar genome structure and individual gene functions, and the apparent absence of genetic recombination. The latter property suggests that evolutionary relationships are not obscured by horizontal transfer of genetic information. Phylogenetic analysis has supported the taxonomic association of these families (Pringle and Easton 1997; see The order *Mononegavirales*). Subsequently the order *Mononegavirales* was extended to include the family *Bornaviridae* (see Borna disease virus, and Pringle 1997). The bornaviruses are vertebrate viruses with monopartite negative-stranded RNA genomes, which have features in common with the other three families in the order. They are substantially different in other properties, however, such as their intracellular location and limited processing of mRNA by splicing. Some disputed evidence suggests that bornaviruses may be associated with human psychiatric disease.

The two genera of viruses, *Ebolavirus* and *Marburgvirus*, classified in the family *Filoviridae* are enigmatic human pathogens thought to be exclusively vertebrate viruses. The classification of these viruses remains in a fluid state due to the hazardous nature of these viruses, which restricts their characterization.

The viruses classified in the family *Paramyxoviridae* are predominantly associated with respiratory disease and childhood illnesses. Two subfamilies have been designated. The subfamily *Paramyxovirinae* comprises the three genera *Respirovirus*, *Morbillivirus*, and *Rubulavirus* described in the Seventh Report, and two newly designated genera; the genus *Avulavirus* accommodating *Newcastle disease virus*, a species now recognized to possess unique properties; and the genus *Henipavirus*, created to accommodate *Hendra virus* and *Nipah virus*, two recently discovered bat paramyxoviruses associated with outbreaks of life-threatening human disease. The subfamily *Pneumovirinae* contains the genera *Pneumovirus* and *Metapneumovirus*, both of which

Table 5 *The taxonomy of negative-sense single-stranded RNA viruses*

The dashes signify 'unassigned.'

contain viruses uniquely associated with respiratory disease of human infants. These two subfamilies are separated by differences in gene number, gene order, and gene size. Unexpected sequence homologies between pneumoviruses and members of the other families of monopartitite negative-sense RNA viruses was one of the initiating factors in the establishment of the taxon of order in virology.

The family *Rhabdoviridae* embraces one of the largest and most catholic of virus families. Four of the six genera include viruses infecting vertebrates. The hosts of rhabdoviruses include plants, invertebrates, and vertebrates, and different rhabdoviruses may multiply in invertebrates and plants, or invertebrates and vertebrates, but none is known which will multiply in vertebrates and plants. The plant rhabdoviruses classified in the genus *Nucleorhabdovirus* are exceptional, being located in the nuclei of infected cells. All other rhabdoviruses are cytoplasmic. Because of their distinctive morphology many rhabdovirsues have been named on evidence from electron microscopy alone. The status of these viruses is unknown since they do not exist as isolates and as a consequence they are not considered in the current taxonomy.

THE SEGMENTED GENOME VIRUSES – THE FAMILIES *ORTHOMYXOVIRIDAE*, *BUNYAVIRIDAE*, AND *ARENAVIRIDAE*

Thee three families of segmented genome viruses have diverse properties and exhibit no common link other than segmentation of the genome. Consequently an order has not been created to embrace these three families. Reassortment of segments may occur among serologically related viruses, a property which can be employed in taxonomy at the species level. Reassortment of segments has been demonstrated in all three families, but in the absence of comprehensive genetic data, the definition of species within a genus is usually

based on serological properties, host range, geographical distribution, and disease association.

The family *Orthomyxoviridae* includes three genera of vertebrate viruses (*Influenzavirus A*, *B*, and *C*) and the genus *Thogotovirus* containing a vertebrate-infecting species and an invertebrate-infecting species. The hemagglutinin-esterase (HE) protein of *Influenzavirus C* exhibits 30 percent amino acid identity with the HE protein of the positive-sense toroviruses, suggesting that genetic information may have passed horizontally by heterologous RNA recombination. Viruses in the genus *Thogotovirus* have six or seven segments and some of their genes exhibit homologies to influenza virus core protein genes. *Thogoto virus*, the type species of the genus *Thogotovirus*, is a biological enigma. The single glycoprotein gene has no homology with any influenza virus gene but does show similarity to the glycoprotein (*gp64*) gene of baculoviruses. The enigma is compounded by the fact that thogotoviruses are tick-borne viruses, whereas baculoviruses are DNA viruses predominantly parasitizing lepidoptera. Since publication of the Seventh Report, a fifth genus, the genus *Isavirus*, has been added to accommodate *Infectious salmon anemia virus*, a pathogen of marine teleosts. Like the mammalian influenza viruses *Infectious salmon anemia virus* possesses an eight-segmented negative-sense single-stranded RNA genome of approximately 14.5 kb. Low sequence homology is exhibited at the amino acid level with the polymerase gene (*PB1*) of *Influenza C virus* (note: the type species of the genus *Influenzavirus C* is designated *Influenza C virus*, etc).

The family *Bunyaviridae* is possibly the most diverse of all the families of viruses, and many trisegmented bunya-like viruses have yet to be classified. Five genera are differentiated at present. Three of the genera, *Orthobunyavirus*, *Hantavirus*, and *Nairovirus*, are regular negative-sense RNA viruses, whereas the remaining two genera, *Phlebovirus* and *Tospovirus*, have one or more segments of ambisense RNA (see). The genera are defined on the basis of phylogenetic divergence, host range and transmission characteristics. Viruses of the genera *Orthobunyavirus*, *Nairovirus*, and *Phlebovirus* are arthropod-transmitted viruses of vertebrates. Viruses of the genus *Hantavirus* are vertebrate viruses with no known invertebrate hosts, and viruses of the genus *Tospovirus* are plant viruses transmitted by arthropods.

The family *Arenaviridae* comprises a single genus of vertebrate viruses with bipartite RNA genomes. Although included in the negative-sense RNA virus category, both segments of the genome have information encoded in an ambisense orientation. Variable amounts of viral complementary RNA, subgenomic mRNA, and cellular ribosomal RNA may be present in purified arenavirus particles.

The positive-sense single-stranded RNA viruses

These viruses have the most expansive taxonomy (Table 6). So far 22 families and 20 unassigned genera have been designated. Plant virus taxa are the most abundant with eight families and 18 unassigned genera, followed by vertebrate viruses with seven families and one unassigned genus. There are three families and one unassigned genus of invertebrate viruses, one family embracing both vertebrate and invertebrate viruses, two families of fungal viruses and one family of bacterial viruses. No positive-sense single-stranded RNA viruses have been isolated from protozoa.

The existence of three 'supergroups' of positive-sense single-stranded RNA viruses has been hypothesized on the basis of common features of genome organization and expression, reinforced by sequence analyses of conserved motifs within the replicase gene (Goldbach and de Haan 1994; Koonin and Dolja 1993; Ward 1993). Families have been clustered into supergroups of 'picorna-like viruses,' 'toga-like viruses' and 'flavi-like viruses,' and variously designated as higher taxa. The 'flavi-like' supergroup, however, is less homogeneous than the other two. None of these proposals has been ratified by the ICTV. The phylogenetic significance of these observations has been questioned recently and is discussed in the section Phylogenetic analysis and taxonomy.

THE FAMILY *PICORNAVIRIDAE*

The family *Picornaviridae* comprises nine genera of vertebrate viruses. The genome is a single molecule of positive-sense single-stranded RNA, 7.0–8.5 kb in size. The overall sequence identity between viruses of different genera is typically less than 40 percent. Most picornaviruses are specific for one or a few hosts, with the exception of the two species, *Foot-and-mouth disease virus* and *Encephalomyocarditis virus*.

The picornavirus species has been defined by the Picornavirus Study Group as a polythetic class of phylogenetically related serotypes or strains which would normally be expected to share: (1) a limited range of hosts and cell receptors; (2) a significant degree of compatibility in proteolytic processing, replication, encapsidation, and genetic recombination; and (3) essentially identical genome maps (see, *Virus Taxonomy, the Seventh Report of the ICTV*, van Regenmortel et al. 2000). As a consequence, the familiar serotypes of picornaviruses have been condensed into a limited number of species. For example, the type species *Poliovirus* of the genus *Enterovirus* includes serotypes 1, 2, and 3, and the type species *Foot-and-mouth disease virus* of the genus *Aphthovirus* includes the serotypes, A, C, O, SAT 1, SAT 2, SAT 3, and Asia 1. The genus *Parechovirus* has been created to accommodate two viruses formerly

Vertebrate virus taxa are indicated by absence of shading.
The dashes signify 'unassigned.'

classified as enteroviruses and known as echovirus 22 and 23. These viruses have predicted protein sequences that have less than 30 percent identity with any other picornavirus. They are now ranked as members of the type species *Human parechovirus*. Since publication of the Seventh ICTV Report, three additional genera have been designated: the genus. *Erbovirus* to accommodate *Equine rhinitis B virus*, which is significantly different from the human rhinoviruses, the genus *Kobuvirus* to accommodate *Aichi virus*, which unlike other picornaviruses exhibits icosahedral surface structure by electron microscopy; and the genus *Teschovirus* to accommodate *Porcine teschovirus*.

The 'picornavirus supergroup' comprises the family *Picornaviridae* and the three families of plant viruses, *Comoviridae, Potyviridae*, and *Sequiviridae*. These families share common features of genetic organization (5′-VPg, 3′-polyA, post-translational cleavage of a polyprotein), similar capsid structure, and sequence similarity of the nonstructural proteins. However, there is no biological overlap and the apparent relationship of these families could equally be a consequence of convergent evolution, modular evolution, or divergence from a common ancestor.

THE FAMILY *CALICIVIRIDAE*

The family *Caliciviridae* includes four genera of vertebrate viruses. The assignment of genera is supported by phylogenetic analysis, and species are distinguished by differences in gene sequence, gene product sequences and serology. The caliciviruses have some properties in common with the vertebrate picornaviruses and the plant comoviruses and potyviruses, for example, a VPg at the 5′ end and a poly(A) tract at the 3′end. The putative viral replicase of the caliciviruses shares sequence homology with that of picornaviruses.

THE UNASSIGNED GENUS *HEPEVIRUS*

Hepatitis E virus, which was loosely associated previously with the caliciviruses on morphological criteria, is now ranked as the type species of an unassigned genus. Phylogenetic analysis of polymerase and helicase regions justifies the separate status of the genus *Hepevirus*. Weak homology is evident with members of the *Togaviridae* (e.g. *Rubella virus*) and the plant furoviruses.

THE FAMILY *ASTROVIRIDAE*

The family *Astroviridae* comprises two genera: *Mamastrovirus* and *Avastrovirus*. The genus *Mamastrovirus* contains four species of viruses infecting mammals, and the genus *Avastrovirus* contains two species infecting avian hosts. Each species includes a range of serotypes; e.g. the seven serotypes of human astroviruses, as defined by immune electron microscopy and neutralization tests, are all included in the type species *Human astrovirus 1*.

THE FAMILY *NODAVIRIDAE*

The family *Nodaviridae* comprises two genera of viruses with bipartitite genomes; the *Alphanodavirus* infecting insects and the *Betanodavirus* infecting vertebrates. *Nodamura virus*, the type species of the genus *Alphanodavirus*, may occasionally infect vertebrates. Seven species are defined within this genus on the basis of a complex of molecular and biological characteristics. The genus *Betanodavirus* comprises seven species of viruses infecting different species of marine fish. There is 10 percent or less amino acid homology between the coat proteins of viruses in the two genera, whereas the level of identity is >80 percent within the genus *Betanodavirus*.

THE NESTED SET GENOME VIRUSES – THE ORDER *NIDOVIRALES*; COMPRISING THE FAMILIES *ARTERIVIRIDAE*, *CORONAVIRIDAE*, AND *RONIVIRIDAE*

The two families of vertebrate viruses, *Coronaviridae* and *Arteriviridae,* and the invertebrate (decapod crustacean) virus family *Roniviridae* are grouped as the order *Nidovirales* by virtue of their distinctive genome organization and similar morphology in the case of the vertebrate viruses (Cavanagh 1997; see The order *Nidovirales*). The mRNAs are processed as a 3′ coterminal (nested) set of subgenomic RNAs. Although the mRNAs are structurally polycistronic, translation is restricted with a few exceptions to the unique 5′ region, which is absent from the next smallest mRNA. Another unique feature of the order *Nidovirales* is the configuration of the replicase gene as two open reading frames with expression mediated by ribosomal frameshifting. The viruses of the two families of vertebrate viruses are not serologically related, but sequence identity may reach 30 percent in selected regions.

The family *Coronaviridae* comprises two genera, *Coronavirus* and *Torovirus*, with little sequence similarity. There is a structural distinction also in that the coronaviruses have a helical nucleocapsid protected by a core shell, whereas the toroviruses have a tubular nucleocapsid. The coronavirus genome is the largest monopartite RNA genome at 27–31 kb in size. Species are distinguished on the basis of serology and sequence comparison. Phylogenetic analyses of gene sequences support the formal taxonomy, even though very high frequency recombination is an attribute of coronaviruses.

The family *Arteriviridae* comprises a single genus, *Arterivirus*. Macrophages are the primary target cells for all arteriviruses and the genus includes the type species *Equine arteritis virus*, and the species *Lactate dehydrogenase-elevating virus*, *Porcine respiratory and reproductive syndrome virus*, and *Simian hemorrhagic fever virus*. Genome strategy and replication pattern are similar to those of the *Coronaviridae*, but the genomes and virions of arteriviruses are about half the size of those of coronaviruses.

THE FAMILY *TOGAVIRIDAE*

The family *Togaviridae* comprises two disparate genera, *Alphavirus* and *Rubivirus*, associated by similar morphology and genome strategy. The species included in the genus *Alphavirus* are serologically related viruses infecting vertebrates and transmitted by mosquitoes. They exhibit a high level of sequence identity (>60 percent in the case of structural protein genes). The single species of the genus *Rubivirus* is a human pathogen with no arthropod vector and no sequence relationship with the alphaviruses.

The replicases of alphaviruses show some sequence homology with the nonstructural proteins of *Hepatitis E virus* and those of several groups of plant viruses, including the families *Bromoviridae* and *Closteroviridae*, and the unassigned genera *Hordeivirus*, *Tobamovirus*, and *Tobravirus*. These constitute the 'toga-like supergroup,' and transcription from genomic and subgenomic RNA is a feature of their multiplication cycle. The closteroviruses possess a toga-like polymerase, but their replication strategy more closely resembles that of the coronaviruses, although the latter have a picorna-like polymerase. These relationships may be a consequence of past recombination events and modular evolution, or merely fortuitous.

THE FAMILY *FLAVIVIRIDAE*

The family *Flaviviridae* comprises three biologically distinct genera. Most viruses of the genus *Flavivirus* are transmitted to vertebrate hosts by arthropod vectors. All

flaviviruses are serologically related. The type species is *Yellow fever virus*. Species are defined on the basis of sequence data, antigenic characteristics, and various biological criteria, and more than 50 species have been designated. Viruses of the genus *Pestivirus* infect ruminants and pigs, have no arthropod vectors, and encode two gene products unique to this genus. Some cytopathogenic isolates of the type species, *Bovine viral diarrhea virus*, have a small insertion of host-derived nucleic acid integrated at a specific site, whereas others have gene duplications or deletions. The genus *Hepacivirus* contains a single species, *Hepatitis C virus*. This virus is transmitted between humans mainly by exposure to contaminated blood. No arthropod vectors are known. Three related viruses isolated from monkeys, *GB virus A*, *GB virus B*, and *GB virus C/Hepatitis G virus* are ranked for the present as unassigned species in the family. Only the latter is associated with hepatitis in humans.

Other categories

The Universal Taxonomy also covers several other agents (Table 7). The family *Narnaviridae* comprises two genera of mycoelements, which exist as ribonucleoprotein complexes but have no virion stage in their multiplication cycle. These have been listed here and also together with the positive-sense single-stranded RNA viruses, because some regard their status as viruses to be dubious. The viroids of plants are now classified as two families, using the suffix *-viroidae* to differentiate them from the true viruses. Finally, consistent nomenclatures for subviral satellites and prions are under consideration.

THE CONCEPT OF THE VIRUS SPECIES

The species is the basic taxonomic group in biological systematics, and because viruses are biological entities the species concept can be extended to virology. Viruses exhibit intrinsic genetic variability due to the error prone processes of nucleic acid duplication. Genetic variability enables biological systems to adapt and survive. As a consequence, unlike chemical compounds, viruses cannot be grouped into universal classes (e.g. species) defined by a single property or set of properties that are both necessary and sufficient for class membership (van Regenmortel et al. 1991). A virus with a positive-sense single-stranded RNA genome is per se a member of a class of positive-sense single-stranded RNA viruses. It could also be a member of several other universal classes defined by morphology, host, antigens, gene order, etc. It follows, therefore, that although viruses can be members of several universal classes, where each class is defined by a single property necessary and sufficient for class membership, the taxonomic grouping designated as a species is not a universal class definable by a single property. Members of a species can only be accommodated in a different type of class, the polythetic class, definable exclusively by several independent properties. In a polythetic class each member possesses most but not all of the properties of the set, and each property in the set is possessed by the majority but not all of the members. The polythetic class definition of a viral species implies that there can be no single defining property for class membership, and search for such a property is unrewarding. Such a property would have to differ from a common property defining a higher category in the taxonomic hierarchy. Common

properties shared by the members of different species, such as are used to designate higher tax (genera, families, and orders), cannot be species-defining properties.

The polythetic definition of virus species (see Definition of taxa) emphasizes the biological nature of viruses and has dispensed with the reference to 'gene pools', which featured in earlier definitions, because most viruses replicate clonally and do not share gene pools. The concept of the replicating lineage, which replaces it, indicates an inherited genealogy extending over many generations, unified by a common descent, and evolving in response to natural selection. The reference to ecological niche occupancy in the definition emphasizes the role of environmental factors (host, tissue tropism, vector specificity, etc.) in determining the identity of species.

This species definition establishes the meaning of the categories used in classification, but it does not provide rules for demarcating the boundaries between species. Nor does it establish equivalence between the diagnostic properties used for delineation of species in different parts of the taxonomy. The phenotypic properties available to define different polythetic classes of viral species are variable in quantity and quality, and progress towards equivalence will be a gradual process (see van Regenmortel et al. 1997).

The high mutability of replicating RNA viruses has led to the development of the 'quasi-species' concept. A quasi-species distribution is the result of self-replication and corresponds to a mutant distribution consisting of a master sequence and an attendant swarm of mutants derived from it. Implicit in the concept of quasi species, however, is the assumption that the species is a unique sequence. This is at variance with the polythetic species concept, which incorporates variability into the definition. Quasi-species distributions have been demonstrated in most RNA viruses at the genotypic level, but nonetheless many RNA viruses exhibit remarkable stability at the phenotypic level, reflecting the existence of powerful selective forces, which maintain an average sequence and genetic stability.

PHYLOGENETIC ANALYSIS AND TAXONOMY

The ascendancy of molecular virology has fostered the conception that viral taxonomy may eventually be reduced to a cataloging and ranking of genome sequences. This is a receding prospect (Mayo and Pringle 1998). Phylogenetic trees derived from nucleotide or inferred amino acid sequences are generally concordant with existing taxonomies over short ranges as noted throughout the section on The Universal System of Virus Taxonomy in this chapter. Furthermore, in monopartite negative-sense single-stranded RNA viruses, where horizontal transfer of genetic information by genetic recombination is rare or nonexistent, sequence relationships can be used to substantiate taxonomic groups up to the level of the order. In particular situations useful inferences can be made about the evolution and origins of viruses (see Virus evolution below), and concerning the mechanics of epidemic diseases. Phylogenetic analysis is less successful in the analysis of more distantly related groups. Polymerase-based phylogenetic trees have suggested previously unsuspected putative links between the polymerases of plant and animal viruses (see The positive-sense single-stranded RNA viruses). However, such data establish relationships between individual genes only and should not be extrapolated to indicate phylogenetic relationships between complete genomes. The genomes of many viruses, particularly RNA viruses, often appear to have evolved in a 'modular' fashion acquiring genes or blocks of genes from the genomes of other viruses or even from their host (for examples, see Mayo and Pringle 1998).

More instructive is the statistical re-evaluation of the worth of RNA-dependent RNA polymerases of RNA viruses as a phylogenetic marker undertaken by Zanotto et al. (1996). The results of a Monte Carlo stimulation assay of sequence similarity among 40 RNA-dependent RNA polymerase and 40 RNA-dependent DNA polymerases were transformed to a gray scale density plot that allowed the significance of the 1 600 possible comparisons to be scanned visually and evaluated statistically by densometric scanning. The concentration of white and light gray squares along the diagonal in the density plots demonstrated that significant values were only obtained between viruses known to be similar on other criteria (i.e. within families). Overall the data do not provide statistical support for proposals for the existence of evolutionary groupings of RNA viruses above the family level (Ward 1993, Koonin and Dolja 1993, Goldbach and de Haan 1994), although they did not negate them. Similarly, this type of comprehensive analysis provided no statistical support for a presumptive common ancestry of viral RNA-dependent RNA polymerases and viral reverse transcriptases.

VIRUS EVOLUTION

The origin and evolution of viruses is too broad a question to consider here. The section on The Universal System of Virus Taxonomy in this chapter indicates that there is no genome strategy or molecular mechanism of processing genetic information that is peculiar to viruses infecting a specific type of host. Viruses leave no fossil record. Where there is evidence of co-speciation of virus and host, however, persuasive estimates of the origin and antiquity of particular viruses can be made (McGeoch and Cook 1994). In general, phylogenetic analysis is hampered by horizontal gene transfer and the absence of isolates from much before the present. The phylogenetic trees for some viruses are merely a

reflection of isolate abundance rather than lineal descent. Where there are obvious relationships but no phylogenetic support, the direction of evolution may be difficult to discern, as for example in the case of the order *Caudovirales* cited in the section on The double-stranded DNA viruses, where convergent or divergent evolution cannot be distinguished (see also Genetics of vertebrate viruses).

More problematic and challenging are the results of recent reverse genetic experiments involving the reengineering of viral genomes. Throughout the order *Mononegavirales* the order of genes is highly conserved. Nonetheless, several gene order variants of vesicular stomatitis virus have been produced by a reverse genetics. Surprisingly, most can be propagated in cultured cells and experimental animals without rearrangement or restoration of the wild-type conserved sequence (Wertz et al. 1997, 2002). Indeed several of the variants slightly exceed the wild-type virus in reproductive potential. It is clear that in the case of RNA viruses at least, strong selective forces maintain an average genome sequence. Until the nature of these selective forces is defined, it will be difficult to arrive at any sound conclusions regarding virus evolution.

INTRODUCTION

Viruses are small quantities of genetic information. This information codes for tools for their multiplication and for a vehicle to go from one site of multiplication to the next. The information can be coded in RNA or DNA. In fact, the information may even be present in the conformation of a particular protein, as in 'prion' proteins, for example, but these are not really viruses. The nature of the viral nucleic acid leads to particular trade-offs that are fundamental to the observed virus morphologies. For the replication of viruses, the genetic information has to be copied by an RNA- or DNA-dependent polymerase. All these polymerases make, on average, one mistake in 10 000 copying steps. This is probably due to the chemical nature of the nucleotide bases, which can exist in two forms, the keto- (lactame-) form and the enol- (lactime-) form (tautomere) (Figure 1a). The equilibrium between these two forms is far towards the keto-form, with an equilibrium constant of 10^{-4}, meaning that there is a chance of 10^{-4} that the nucleotide is in the enol-form when the polymerase passes to place the complementary base. Normally, guanines pair with cytidines but not with thymidines (as shown in Figure 1b). However, a thymidine in the enol-form can base pair with a keto-guanine and form three hydrogen bonds (Figure 1c). The same holds for the other bases: keto-A can pair with enol-C, keto-C with enol-A, and keto-T with enol-G. Therefore, the polymerase will add a wrong base when the template base is in the enol-form. DNA-dependent polymerases have a proofreading activity that corrects these errors in base pairing, leading to error frequencies in DNA organisms of only about 10^{-7} per copied base. This means that DNA virus genomes are rather stable and the genomes of DNA viruses can be large, ranging from about 5 000 (polyomavirus) to 200 000 base pairs (herpes- and poxviruses), the largest genomes belonging to the phycodnaviridae, algal DNA viruses with genomes up to 560 kbp (Yan et al. 2000; Sandaa et al. 2001; van Etten et al. 2002), certain bacteriophages, such as phage G of *Bacillus megaterium*, which packages ~670 kbp (Hutson et al. 1995), and the latest champion, a virus found in ameba with a genome size of about 800 kbp (La Scola et al. 2003). These large viral genomes are bigger than those of the smallest bacteria, such as mycoplasma (580 kbp, Fraser et al. 1995). However, RNA-dependent RNA polymerases usually do not have a proofreading activity (or only a rudimentary form of it). This means that for an RNA virus with a genome of 10 000 nucleotides, on average every offspring virus will have one mutation. Because selection mechanisms cannot function with more than one mutation per offspring virus, this limits the genome size of RNA viruses to about 10–20 000 nucleotides, the only exception being the coronaviruses that have a positive-strand RNA genome of between 27 and 32 kb (Lai and Holmes 2001). Note that the amount of information space that a virus can attribute to coding for its transport vehicle depends on the total amount of information space. Therefore, RNA viruses have capsids with, in general, simpler structures with fewer structural proteins than DNA viruses. Also, because of the genome size, the space inside a DNA virus capsid has to be larger than that for an RNA virus, leading to more elaborate capsids for DNA viruses.

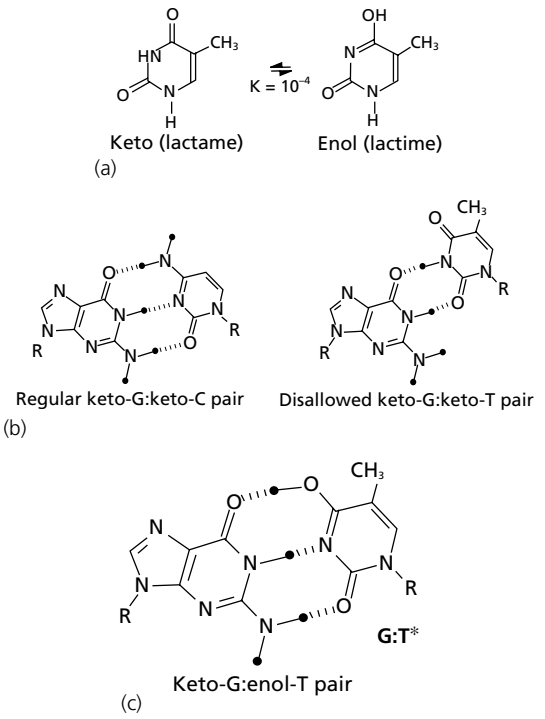

Figure 1 (a) *Keto–enol tautomerism of nucleotide bases.* **(b)** *Allowed and disallowed nucleotide pairs.* **(c)** *Allowed keto-G:enol-T pair.*

RNA viruses usually only code for the necessary transport and replication proteins, plus often for a protein that counters or avoids the effects of innate immunity. Apart from proteins analogous to those encoded by the RNA viruses, the larger DNA virus genomes also code for a considerable number of ancillary proteins that modify the host metabolism, and also for immunity-modifying factors.

The replication component of RNA viruses may consist of the naked nucleic acid. When positive-strand RNA viruses enter the cell, the vRNA is directly translated into viral proteins. For this effect, the vRNA contains a specific three-dimensional (3D) RNA structure, the internal ribosome entry site (IRES), to which host translation factors bind in order to start viral protein production (Kieft et al. 2001; Sarnow 2003). However, sometimes protein components are needed for the first steps in the replication process. Retroviruses need reverse transcriptase and integrase for insertion of the transcribed DNA into the genome of the host cell, and negative-strand RNA viruses have a viral RNA that does not directly code for proteins but which has to be transcribed into mRNA first. For this function, negative-strand RNA viruses assume a unique structural composite in which the viral RNA is stoichiometrically bound to the nucleoprotein. This helical nucleocapsid, rather than the naked vRNA, is the template for transcription and replication. The viral RNA-dependent RNA polymerase is bound to this helical template, either directly (influenza virus) or with the help of a phosphoprotein (all nonsegmented negative-strand RNA viruses). This complex structure enters the infected cell and is directly active in transcription. Thus, if a virus needs a virus-specific process at the start of its replication cycle, the proteins needed for this process have to be packed inside the virus particle.

The transport component protects the virus when it is outside a cell. This component contains a receptor-binding protein (or proteins) and sometimes also proteins needed for release from the infected cell. The surface of the virus is also involved in cell entry by membrane fusion (for the membrane or enveloped viruses) or by some other membrane penetration mechanism (for nonenveloped viruses). Because of the limited genome size for encoding protein subunits, viral transport components often exploit symmetry in order to make a 3D structure from many copies of only a few building blocks. There are two major types of symmetry used by viruses: helical symmetry (mainly plant viruses and bacteriophages, bacteriophage tails and the above-mentioned nucleocapsids of negative-strand RNA viruses) and icosahedral symmetry (many small positive-strand RNA viruses, small and large DNA viruses, and bacteriophage heads). The small icosahedral viruses have very simple capsids with only one type of protein, or with three or four closely related proteins. The large icosahedral viruses, such as adenoviruses and herpesviruses, have more complex capsids with several major capsid proteins arranged into topological units, usually pentameric and hexameric, called capsomers, plus a number of small proteins that glue the capsomers together. There are icosahedral viruses with a single protein capsid layer (rhinovirus, hepatitis B virus) and a double protein layer (reoviruses), and there are also icosahedral viruses that have a membrane with proteins both outside and inside the membrane (togaviruses and alphaviruses).

However, many enveloped viruses do not have icosahedral symmetry and formation of the virus particles takes place in a different manner. All negative-strand RNA viruses, the positive-strand coronaviruses and, most likely, the retroviruses (although there is still some debate about this point), are not icosahedral.

An interesting feature of the transport components of certain viruses is that they must be stable enough to form inside the infected cell and to resist attacks in the extra cellular environment, but that they have to fall apart when the virus enters a new cell. This implies that the conditions present during virus formation (encapsidation) must be different from those during decapsidation. Different viruses solve this problem in different ways. Viruses such as HIV undergo cleavage of the GAG polyprotein inside the virion by a virus-encoded protease for maturation. It is the immature, intact GAG polyprotein that is assembled in the infected cell and the mature, cleaved capsid that will fall apart upon cell

entry. Influenza viruses code for a membrane channel that allows acidification of the virus interior when it passes through the acidic endosome upon entry. Acidification not only leads to membrane fusion by the hemagglutinin, but it also loosens the interactions between the matrix proteins inside the virus (Hay et al. 1985; Martin and Helenius 1991). Adenoviruses are uncoated in a stepwise fashion: the viral protease is activated by two sequential events, first interaction of the receptor-binding protein with the cellular receptor (an integrin), and then activation of the protease by the reducing environment inside the cytoplasm. This leads to sequential loss of viral proteins and degradation of the core necessary to release the viral DNA for transport through the nuclear pore (Greber et al. 1996).

HELICAL VIRUSES AND HELICAL VIRAL COMPONENTS

One of the symmetries used by viruses in order to build a capsid from repeating units is helical symmetry. The characteristics of a helix are defined mathematically by two parameters: u corresponds to the number of subunits per turn (often not an integral number) and p is the axial rise per unit (Figure 2). The pitch (P) of a helix corresponds to the distance along its length that has to be traveled to reach the next subunit, i.e. $P = u \times p$. Helical structures can have a rotation axis coincident with the helix axis, like the tail of bacteriophage T4, which has sixfold symmetry and is made by stacked rings with a rotation angle of 60° between subsequent rings. If a helix is perfect, then a single view of the helix will give all the 3D information of the protein and nucleic acid components that make up the helix, because the same protein can be observed along the helix but in different orientations. Different types of helices can exist in virus particles:

- The nucleic acid can be associated with and protected by many copies of a single protein and form an infectious virus particle. In these helices the protein serves to protect the nucleic acid. Examples are the tobamoviruses (tobacco mosaic virus (TMV)); Figure 3), tobraviruses (tobacco rattle virus), hordeiviruses (poa semilatent virus (PSLV) and lychnis ringspot virus (LRSV)), furoviruses (potato mop-top virus (PMTV)) and pecluviruses (peanut clump virus). These viruses are all rod-like positive-strand RNA viruses. Other examples are the badnaviruses, bacilliform double-stranded DNA plant viruses such as sugarcane bacilliform virus (SCBV-IM). Sometimes, proteins with specific functions are added at one or both ends, as is found with single-stranded filamentous DNA bacteriophages such as Pf1 and M13.
- The nucleic acid can be associated with many copies of the same protein and form the matrix for transcription and replication of the nucleic acid, but other proteins and a lipid membrane are needed to complete the virus particle. Good examples of this kind of structure are the nucleocapsids of negative-strand RNA viruses (see under Nonsymmetrical viruses ; Figure 9, p. 15). However, under physiological conditions these helical structures are very flexible and do not have defined helical parameters.
- The helix is not associated with the nucleic acid but is part of the virus structure, like the tail of double-stranded bacterial DNA viruses such as bacteriophage T4 that is used for injecting the nucleic acid into the bacterial host cell (Figure 4).

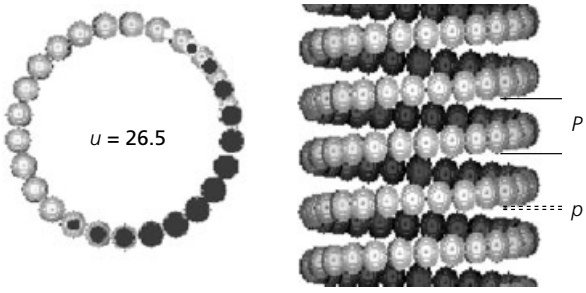

Figure 2 *Schematic representation of a helix.* P *is helical pitch,* p *corresponds to the axial rise per unit, and* u *is the number of subunits per helical turn.*

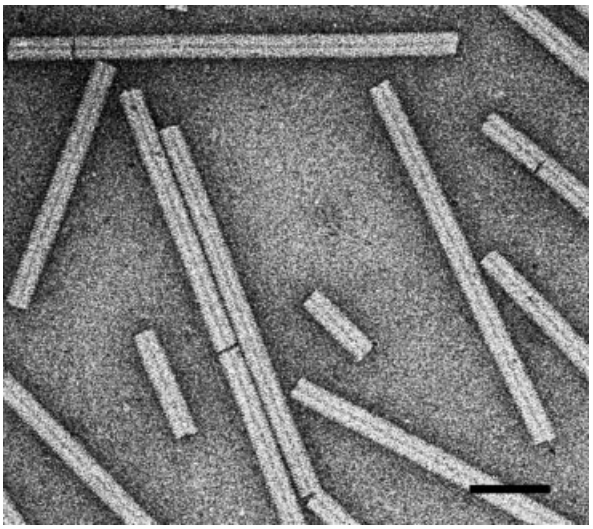

Figure 3 *Electron micrograph of tobacco mosaic virus negatively stained with 1% uranyl acetate. The bar corresponds to 100 nm.*

In principle a helix can have more than one start (like microtubules), but in the case of a helix associated with nucleic acid the helix has always a single start because as there is only a single nucleic acid molecule.

Methods to study helical virus structures

Electron microscopy (EM) is probably the best method to visualize helical viruses or viral components. TMV

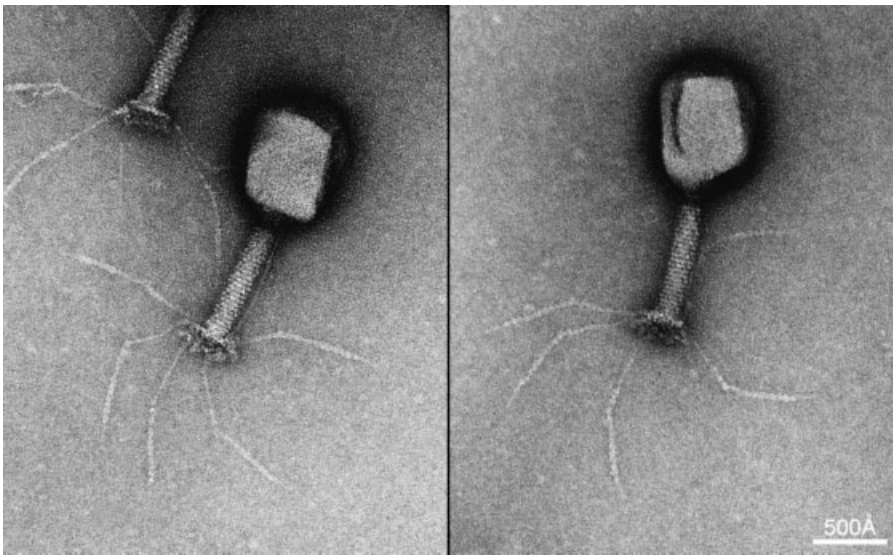

Figure 4 *Phage T4 visualized by negative-stain EM. The extended icosahedral head is crumpled by dehydration but the thick contractile tail is well preserved, as are the long tail fibers that extend from the baseplate. Short tail fibers are also visible underneath the baseplate. Figure courtesy of M.E. Cerritelli, N. Cheng, and A.C. Steven, LSBR-NIAMS-NIH.*

was one of the first biological objects to be observed in EM (Horne et al. 1939). For negative-stain EM, virus specimens are first absorbed on to a support film that is transparent to electrons, for example a thin film of evaporated carbon. The embedding of the helix in a layer of stain gives high contrast and makes it possible to visualize the pitch of the helix (Figures 3 and 4). If the stain stays low on the carbon only one side of the helix is visualized, but the stain may also cover the side of the helix that does not touch the support film. Another method of preparing virus for EM is to evaporate a thin film of metal at an angle over a dried sample on support film. Differences in sample height will lead to differences in metal deposit and, hence, in contrast. Because metal shadowing outlines only one side of the helix, this method gives information on the handedness of the helix (right or left turning). The virus can also be prepared by fast freezing of the virus in a very thin film of buffer – so-called cryo-electron microscopy (cryo-EM), leading to a state of the virus particle that is close to its native form in solution. The picture obtained from cryo-EM is a two-dimensional (2D) projection of the 3D structure of the virus. The disadvantage of this technique is the very low image contrast that makes it necessary to use image analysis in order to enhance the signal-to-noise ratio. In principle, cryo-EM may lead to subnanometer structural information on viruses.

The Fourier transform of the 2D projection of a helix gives a characteristic diffraction pattern in which the information is situated on lines, the layer lines. Analysis of the diffraction pattern leads to total definition of the helical parameters and can be used to recalculate a 3D model of the helical structure. For this approach the cryo-method is the most useful way to prepare the virus sample for EM. However, this analysis method is difficult and time-consuming. Recently, new algorithms have been developed for the reconstruction of helical filaments using single-particle methods (Egelman 2000; Li et al. 2002). This technique uses iterative real-space reconstruction and is able to overcome most of the problems that can be encountered in helical reconstruction using Fourier analysis, which is more dependent on long-range order.

Another method for the analysis of helical structures is fiber diffraction, for which a sample has to be prepared in which the helices are all aligned in the same direction. Well-aligned fibers can be prepared by drying a gel of purified helical virus under controlled humidity and temperature conditions in a strong magnetic field (Nave et al. 1979, 1981), which is then analyzed by X-ray diffraction. The structure of TMV was solved to a resolution of 3.6 Å with this technique (Namba and Stubbs 1986). TMV contains a single molecule of single-stranded positive-strand RNA plus 2 130 copies of a single coat protein of 17.5 kDa. The pitch of the helix is 23.0 Å, with 16.33 subunits per turn and three nucleotides per protein subunit. The RNA is squeezed in a groove between protein subunits of subsequent helical turns and follows the helical path at a radius of 40 Å.

ICOSAHEDRAL VIRUSES

The high symmetry of the icosahedron offers similar advantages to the helix for capsid architecture, including maximizing packaging volume for the viral genome at a minimal cost in coding space by making use of repeated protein subunits (Crick and Watson 1956). In a simple icosahedron 60 identical subunits are arranged in a

closed shell with fivefold axes of symmetry at the 12 vertices, threefold axes on the 20 facets, and twofold axes on the 30 edges (Figure 5). Each subunit has equal contacts with its neighbors. However, most icosahedral viruses use elaborate variations on this scheme to construct larger and multifunctional capsids by coding flexibility into the subunits that allow non-identical interactions, as described below, which introduce additional sites of local hexameric symmetry. Consequently, these structures are useful model systems for studying protein folding and assembly, and the flexibility of subunit interfaces.

Viruses from all walks of life have icosahedral capsids, although a spectacular range of variations is observed in their structural details. General principles about assembly, maturation and function of these viruses might best be listed as a menu of strategies from which a combination may be chosen to describe particular cases. For example, the nature of the genome may be RNA or DNA; single- or double-stranded; its recruitment by packaging into a preformed capsid through a specialized vertex, or capsid assembly around a genomic or pregenomic complex; delivery by capsid entry into the cell or by some membrane-penetrating mechanism from an external membrane-anchored location. Structural variations include possible use of a scaffold for capsid assembly, which may be internal or external; proteolysis of structural proteins during capsid maturation; reorganization of the capsid proteins, which may lead to a change in the capsid diameter; the possible incorporation of a membrane, which may be external to the capsid or internal (or sandwiched between protein shells); host recognition by fibers protruding from the capsid surface or by the capsid surface itself; and so on.

One element remains central to the many aspects of the virus lifecycle, and that is the symmetric capsid. This icosahedral protein complex serves a variety of functions, the most obvious of which is as a protective container for the transport of the viral genome from one cell to another. However, various roles are observed for capsids, including interaction with other virus proteins (connector-tail complex, fibers, tegument, membrane-

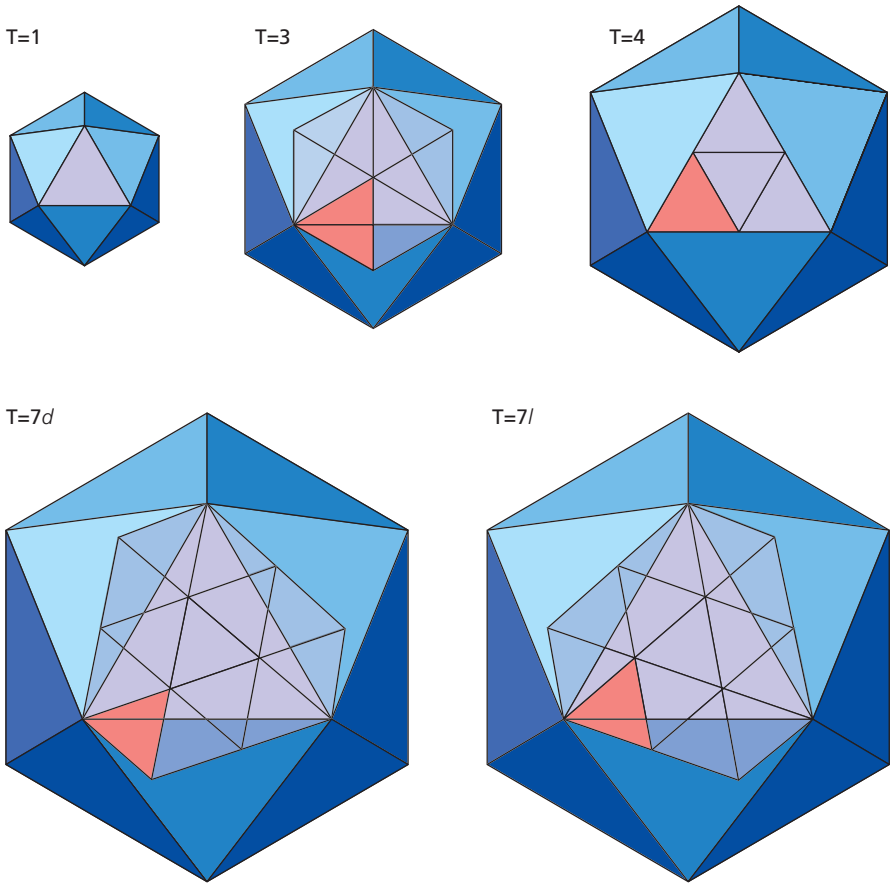

Figure 5 *Icosahedral geometry. An icosahedron has 20 triangular facets bounded by the five-fold symmetrical vertices of the icosahedron. By tiling the icosahedral surface with triangles, as shown for different Triangulation numbers 3–7, larger volumes may be enclosed. Additional hexavalent sites are created where triangular vertices meet. Skew symmetries, such as T = 7, may be 'handed' and both laevo* **(l)** *and dextro* **(d)** *forms are observed in viral capsids (see Figure 6, p. 8). The largest T-number observed to date is in the capsid of PBCV-1 (Yan et al. 2000) with T = 169.*

bound glycoproteins), transcriptional compartment, receptor recognition, and genome release through disassembly. The capsid itself may be as simple as a single-species assembly (e.g. hepatitis B virus (HBV)) or include a number of structural components (e.g. herpes simplex virus (HSV)), and generally the complexity is observed to increase with size.

Recent work has revealed some particular elements of capsid structure and function that are common to seemingly quite unrelated viruses. One example is the remarkable similarity in structure between phage PRD1 and the mammalian adenovirus, which extends from capsid architecture to the structures of the major capsid proteins, P3 and hexon, respectively (Benson et al., 1999, 2002). Another example is the similarity between phage T4 and HSV, including the recent discovery of a specialized vertex on the capsid of HSV-1 that is implicated in uptake of the dsDNA genome (Newcomb et al. 2001), analogous to the way in which tailed dsDNA phage capsids package their genome through a unique 'connector' complex prior to attachment of their tail structure. The fold of the capsid protein is also conserved in viruses from a wide variety of sources – for example, the 'jelly roll,' an eight-strand β-barrel, is found in RNA and DNA viruses from bacteria, plants, insects, and animals. In such cases, the study of structure has led not only to an understanding of virus function, but also to the possibility of extensive evolutionary relationships.

An outline of icosahedral architecture is given below, including examples of contrasting systems to highlight connections between structural features and function.

A note on methodology

Electron microscopy has played an important role in visualizing virus structure, starting from the development of the negative-stain technique (e.g. Brenner and Horne 1959), to which the methodology of image reconstruction was subsequently applied (Crowther et al. 1970) for extending structural analyses of icosahedral viruses into three dimensions. Cryo-EM now substitutes for negative staining and avoids dehydration, fixation, and staining artifacts (Adrian et al. 1984). Although EM has been important in studying virus structure, it is equally true that the highly symmetric structure of icosahedral viruses has made them invaluable for the development of 3D structural analysis methods for cryo-EM data. This synergy has led to achievements of subnanometer resolution for several icosahedral capsids (Bottcher et al. 1997; Conway et al. 1997; Mancini et al. 2000; Zhang et al. 2002; Zhou et al. 2000), with the expectation of higher resolution in the future (see Baker et al. 1999b for a recent review of such structural analyses). X-ray crystallography has also been applied to whole capsids (Hogle et al. 1985; Johnson and Chiu 2000), although this kind of analysis remains challenging owing to the large size of the particles leading to large unit cells and, thus, very close packing of diffraction spots. A combination of these two techniques is often employed wherein subunit atomic models from crystallography are placed into a lower-resolution structure of the complex from cryo-EM (Chiu and Rixon 2002; Modis et al. 2002). This hybrid approach, although not atomic in resolution, is nonetheless valuable for situations where crystallization is difficult or impossible. Examples include capsids decorated with antibodies or Fabs (Prasad et al. 1990; Porta et al. 1994; Conway et al. 2003), capsids decorated with receptor fragments (Hewat et al. 2000; Rossmann et al. 1994), and even capsids alone based on subunit models (Speir et al. 1995; Martin et al. 2001; Modis et al. 2002). Another hybrid approach is the use of cryo-EM density maps as phasing models to initiate crystallographic analyses (e.g. Speir et al. 1995; Grimes et al. 1998).

The nonsymmetric components of a virus, such as membranes and nucleic acid, are generally not visualized by these methods and so less is known about the structures they adopt. The problem is one of low signal and high noise; information from many identical copies must be averaged together to yield an interpretable structure by cryo-EM or X-ray crystallography, and this is clearly impossible to do with the nonuniform pieces. Several exceptions have been observed, however, although these are consequences of association with the icosahedral capsid. One is regions of packaged RNA that contact the capsid and which are visualized by crystallography, for example at icosahedral twofold axes of the nodamura viruses, Flock House virus (Fisher and Johnson 1993), and pariacoto virus (Tang et al. 2001), where they appear to influence the interface between capsid proteins and determine in part the $T = 3$ capsid geometry, and at the transcribing vertices of bluetongue virus cores (Gouet et al. 1999). Another is the highly concentrated dsDNA of bacteriophages, which appears as organized layers spaced ~25 Å apart in cryo-EM images, and as concentric shells of DNA in image reconstructions, which, although somewhat artificial owing to the imposition of symmetry, nonetheless appears to have some bearing on the genome organization within the capsid (Cerritelli et al. 1997; Olson et al. 2001). A similar spacing has been observed for herpes virus DNA (Booy et al. 1991), although the ordering does not appear on the global scale of the phage DNA.

The icosahedral capsid

Icosahedrally symmetric capsids come in various degrees of complexity, from the small and simple, such as capsids of parvoviruses that are built from 60 copies of (essentially) a single protein, to the large and complex, including those of herpesviruses, which comprise 960

copies of the major capsid protein and hundreds of copies of several other structural proteins. Capsids may be multilayered, such as those from rotaviruses and reoviruses, with different copy numbers of the constituent proteins in each layer. How is this variation consistent with icosahedral symmetry, which strictly demands 60 identical asymmetric units? And how might the 960 copies of the major capsid protein of HSV, for example, be subdivided into 60 asymmetric units of 16 copies each and arranged identically to form a closed shell? The prevailing explanation is the concept of 'quasi equivalence' (Caspar and Klug, 1962; Johnson and Speir, 1997), in which identical subunits are placed in slightly different chemical environments according to their position within the asymmetric unit. The different numbers of subunits may be described by a 'triangulation number,' T, which is a count of the number of triangles that may be used to tile an icosahedral facet so that each triangle accounts for the positions of three protein subunits (Figure 5). A triangulation number T = 1 corresponds to perfect icosahedral symmetry with each subunit in an identical environment. A selection rule determines the allowable triangulation numbers as follows: $T = h^2 + hk + k^2$, where h and k are integers 0, 1, 2, ... The total number of subunits is then 60T. The capsid surface is triangulated by pentavalent positions at the vertices and hexavalent positions elsewhere (except in the case of T = 1). Certain T numbers are forbidden, such as T = 2, although this number has been used to describe protein shells from dsRNA viruses (yeast L-A virus – Cheng et al. 1994; Caston et al. 1997, and the cores of some multilayer capsids; see below) with 120 copies of a capsid protein subunit arranged as 60 asymmetric dimers. Some extensions to this simple geometric descriptor have been developed to account for more complex structures. One is the pseudo-T number, where the subunits are non-identical, for example in the case of picornaviruses, which have three similar but non-identical capsid subunits arranged in a pseudo-T = 3 lattice (Arnold and Rossmann, 1990), and adenovirus, which has pseudo-T = 25, where the hexavalent positions are occupied by trimers and the pentamer subunits on the vertices are a different protein. Another is the addition of a second triangulation number, Q, that is used to describe the geometry resulting from one or more additional 'bands' of subunits around the equator in elongated capsids such as that of bacteriophage T4 (T = 13/Q = 21) (Aebi et al. 1976).

The concept of quasi equivalence has therefore had to adapt to the various ways in which flexibility between subunits contacts is expressed in virus capsids. In some cases this flexibility involves rather larger departures from symmetry than those originally envisaged. The 'forbidden' T = 2 capsid described above is one example. Another is the capsid geometry of SV40, a *Polyomavirus* in which pentameric capsomers occupy both hexavalent and pentavalent sites in a T = 7 geometry (Liddington et al. 1991). This architecture, common for all polyoma and papilloma viruses, utilizes just 360 copies of the capsid protein (corresponding in quantity to the forbidden T = 6) instead of the expected 420, and involves different conformations for the C-terminal arms that interface with (and invade) neighboring capsomers (Figure 6a). A third kind of departure is observed in the hexameric capsomers of some T = 7 dsDNA bacteriophages, such as λ, T7, P22, and HK97, which obey 'classic' hexamer and pentamer capsomer structure (Figure 6b, c). The hexamers of the early assembly forms of these capsids exhibit a marked departure from local sixfold symmetry, but this is 'cured' upon maturation (Dokland and Murialdo 1993; Conway et al. 1995; Lata et al. 2000). Recently a structure of the procapsid form of an animal virus, HSV-1, has been solved and this shows similar, although less pronounced, changes for the hexameric capsomers during maturation (Heymann et al. 2003; Trus et al. 1996). Yet another example of low quasi equivalence comes from the geminiviruses, plant viruses with double heads of partial T = 1 icosahedra fused at a ring of five vertices (Zhang et al. 2001).

The flexibility of capsid proteins at subunit interfaces must also, in some cases, accommodate mismatches in symmetry. A well-known example of this is from tailed bacteriophages, where a 12-subunit connector complex occupies one of the vertices of the capsid, a site of icosahedral fivefold symmetry. The connector is thought to nucleate assembly of the capsid, after which DNA is packaged through it followed by attachment of the tail. The mismatch has been proposed to allow rotation of the 12-fold connector within its fivefold 'bearing' as part of the DNA-packaging (Simpson et al. 2000), in line with rotational functions implicated in other symmetry mismatches (Beuron et al. 1998; Junge et al. 2001; Thomas et al. 1999). However, rotation is not always implicated in symmetry mismatches: for example, it has no obvious role in the mismatch between the penton base of adenovirus and the trimeric fiber that binds to it.

Connectorless capsids may also exhibit large-scale symmetry mismatches, as in the case of some dsRNA viruses which have an inner core that exhibits the forbidden T = 2 geometry and is surrounded by an outer layer with T = 13 geometry (reovirus – Reinisch et al. 2000; bluetongue virus – Grimes et al., 1998; *Rotavirus* – Lawton et al., 1997; phi6 – Butcher et al. 1997). The subunit interactions between the layers involve non-equivalent contacts that are additional to those within each layer.

Icosahedral capsid protein folds

The most commonly observed fold for capsid proteins is the eight-strand β-barrel mentioned above, first seen in tomato bushy stunt virus (Harrison et al. 1978) and later

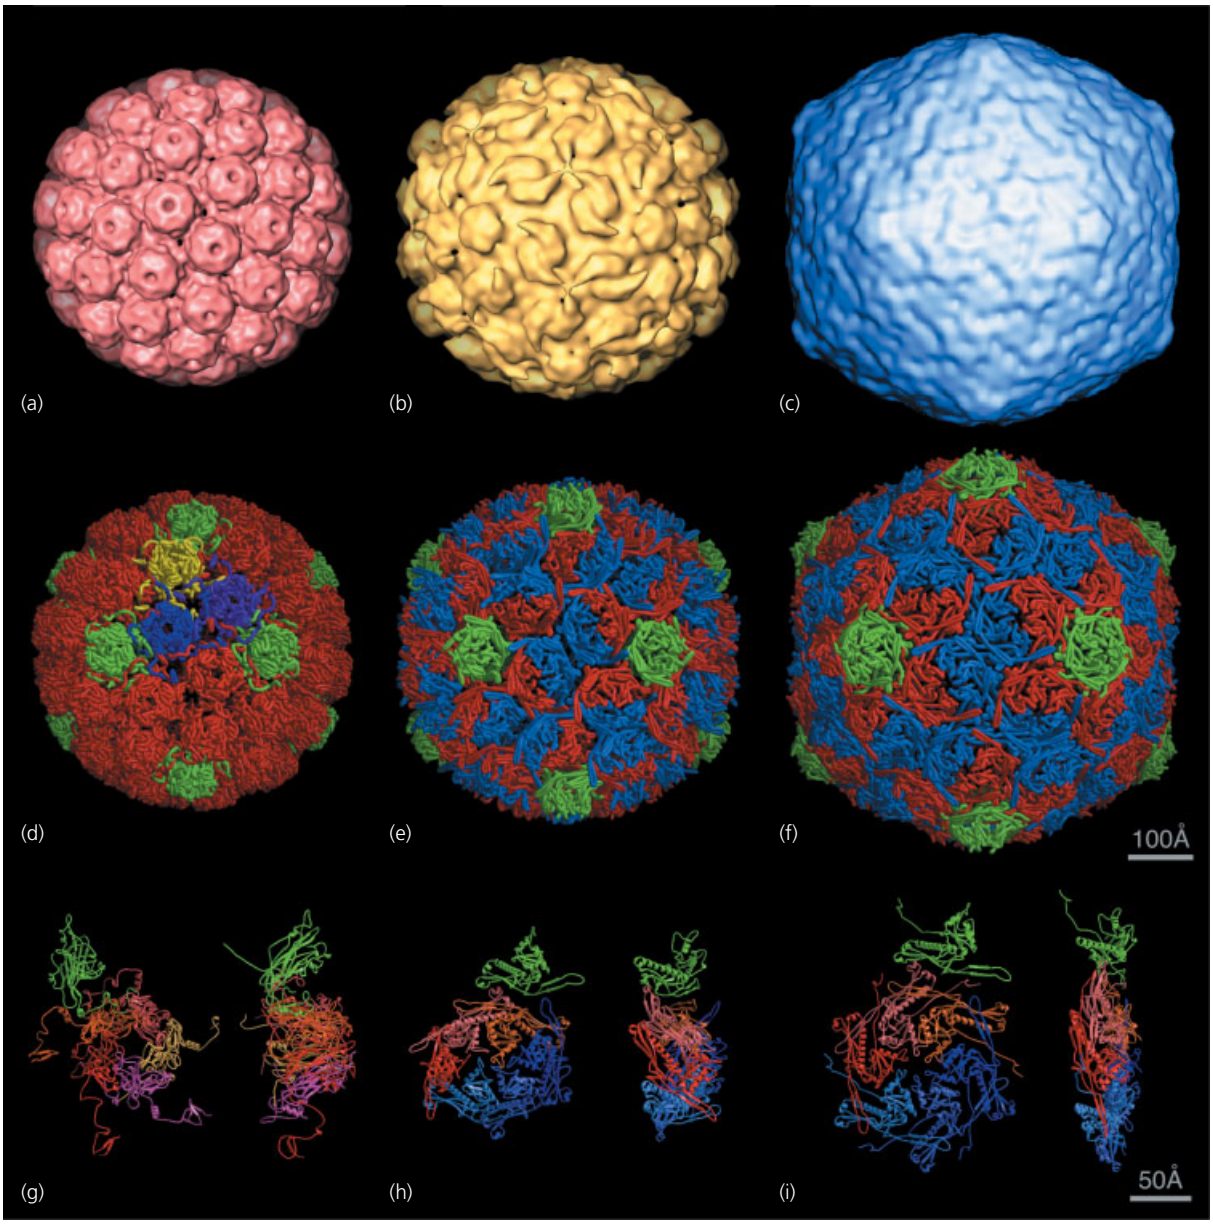

Figure 6 *Capsids with T = 7 geometry include polyomaviruses and lambdoid bacteriophages. The atomic model for SV40 (Stehle et al. 1996; PDB Id: 1SVA) is rendered as a surface at 16 Å resolution in panel* **(a)**, *showing the capsomers as protruding knobs in either pentavalent or hexavalent positions and with the right-handed, or T = 7*d, *configuration. Cryo-EM reconstructions of the procapsid (16 Å – Conway et al. 2001) and mature capsid (24 Å – Conway et al. 1995) of bacteriophage HK97 are shown in panels* **(b)** *and* **(c)**, *respectively. In this case the surface lattice has opposite hand, T = 7*l, *and the capsomer appearance, although similar to SV40 at the vertices (pentavalent positions), is quite different elsewhere. In particular, the HK97 procapsid shows only local twofold symmetry at the hexavalent sites, whereas the mature capsid shows good six-fold symmetry. The procapsid expands into the mature form during packaging of the dsDNA genome: this remarkable transformation involves a coordinated change in subunit interactions between the 420 copies of the capsid protein. When rendered as tubes, the SV40 capsid* **(d)** *reveals that all capsomers are pentamers, unlike many T = 7 capsids, such as that of HK97, which has a combination of pentamers and hexamers. In* **(d)**, *pentamers at the vertices are colored green, and the rest are red, except for three on a frontmost facet of the icosahedron that are colored blue, purple, and yellow to distinguish them. The HK97 procapsid model* **(e)** *is pseudoatomic, resulting from fitting an atomic model of the mature capsid protein into a 12 Å resolution cryo-EM model of the procapsid (Conway et al. 2001). As for SV40, capsomers at the vertices are green, but the hexameric capsomers are colored as one trimer in red and the other in blue to highlight the local two-fold symmetry. The mature capsid* **(f)** *is from a crystallographic model (Wikoff et al. 2000) and is colored as for the procapsid. Ribbon diagrams of the asymmetric units are shown at the bottom in each case – a top-view at left and a side-view at right – including one subunit from pentavalent capsomers in green and the others in shades to match the views in the middle row. For SV40* **(g)** *the extended carboxy termini are involved in interactions between capsomers. The views of HK97 procapsid* **(h)** *and mature capsid* **(i)** *show the more regular hexon in the mature form, as well as flattening and thinning of the capsomers.*

in picornaviruses and other positive-strand RNA viruses (Rossmann and Johnson 1989) from animals, plants, and insects. It has been seen subsequently in dsDNA viruses, including hexons of adenovirus (Roberts et al. 1986) and phage PRD1 (Benson et al. 1999), and in the enzymatically active cores of dsRNA reoviruses (Grimes et al. 1998; Reinisch et al. 2000), although these also have additional domains that include significant amounts of α-helix. Perhaps surprisingly, the architecturally related yeast L-A virus, which adopts the same arrangement of 60 asymmetric dimers (Cheng et al. 1994; Caston et al. 1997) with similar overall shapes and dimer interface contacts (Naitow et al. 2002), does not, however, share the same fold as the reovirus cores.

Folds with predominantly α-structures are less commonly observed. One example is the capsid of HBV, where the protein dimer interface is a four-helix bundle (Bottcher et al. 1997; Conway et al. 1997; Wynne et al. 1999), including a helix–turn–helix contributed by each of the two subunits (Figure 7). A similar motif has also been observed in HIV-1 CA protein dimers (Gamble et al. 1997; Zlotnick et al. 1998), although HIV does not conform to icosahedral symmetry. A recently solved 65 kDa fragment of the 150-kDa major capsid protein of HSV-1 and located in the upper domains of the capsomers is also predominantly α-helical (Bowman et al. 2003). Few structures are available for the capsid proteins of the widespread dsDNA phages, but those for HK97 (Wikoff et al. 2000) (Figure 6i) and P22 (Jiang et al. 2003) are similar, although they have no structural homology with any other proteins solved to date.

Capsid assembly

From the descriptions above of icosahedral symmetry and the variety of departures from it, we must suppose that capsid assembly is directed so as to achieve the correct structure in each case (Dokland 2000). Overexpression of capsid proteins sometimes results in multiple and deviant assembly forms, including tubes (e.g. Lepault et al. 2001), and closed shells of various sizes (e.g. Salunke et al. 1989), clearly the result of non-native conditions and elevated concentration. Assembly of 60-fold subunits to form a specific capsid structure is a complex process involving at least the following steps: onset (e.g. nucleation); accumulation of identical subunits into non-identical positions within a specific architecture; and completion of the capsid by closing the shell. At some stage in this process the non-structural elements, including the genome, must be packaged, and additional maturational events may also occur, including proteolysis of the capsid protein, reorganization of the subunits in the completed capsid, and additional stabilization of the capsid through binding of accessory proteins or some other modification of the subunit interactions. Assembly is generally not well understood, particularly the stages before completion of the capsid.

Innate curvature between subunits offers a framework for constructing a container, although it may be insufficient for specifying a particular geometry or even producing closed surfaces. Smaller icosahedral viruses generally have one capsid protein (or several but with largely similar folds), and these are often capable of self-assembly into virus-like particles in expression systems. Larger capsids, such as that of HSV (Nicholson et al. 1994), assemble with the aid of a scaffold that does not itself obey icosahedral symmetry but which presumably enforces the correct curvature on the assembling subunits and is later removed. Likewise, the outer T = 13 shells of dsRNA viruses are organized by self-assembled T = 2 cores, although these cores are essential to the virus and remain in place. For the *Alphavirus* Sindbis the capsid proteins do not appear to interact strongly with each other, but instead the association of the amino-terminal domain with the genomic ssRNA is the organizing force for assembly (Zhang et al. 2002). In this case, the capsid is surrounded by a membrane penetrated by coiled-coil domains of heterodimeric E1 and E2 glycoproteins that conform to the T = 4 geometry of the underlying capsid. These may also be involved in specifying the correct assembly state of the virus. Similar organization is possible in other alphaviruses, such as Ross River virus and Semliki Forest virus, as well as the more distantly related *Flavivirus*, tick-borne encephalitis virus, which shares structural homology in parts of the glycoprotein.

The necessity for a scaffold appears to be related to capsid diameter, with the limit being approximately 500 Å. Some dsDNA phages of this size, such as λ and P22, require a scaffold, whereas others do not, as is the case for HK97. In the absence of the scaffold protein, phage P22 capsid protein assembles mostly into aberrant particles with T = 4 geometry, as well as some with the normal T = 7 (Thuman-Commike et al. 1998), demonstrating that the flexibility between protein subunit interactions, which serves to allow non-equivalent bonding arrangements in the capsid, must also be controlled to avoid non-productive assembly.

Any internal scaffolding must be expelled to allow space for the genome. In some cases the scaffolding protein is proteolysed, presumably to aid its egress, and often by a virally encoded protease. In the case of HSV, the scaffold and protease genes overlap, ensuring colocalization of protease with the substrate scaffold protein. Phage HK97 apparently has no distinct scaffold protein – one of the largest icosahedral virus to forgo this assembly component – but the capsid protein includes an amino-terminal ~100 residue domain that is proteolysed after assembly and which is proposed to contain the scaffolding function (Conway et al. 1995). In other cases, such as phage P22, the scaffold protein is not proteolysed but none the less exits through holes in the procapsid surface and is recycled to construct new capsids (King and Casjens 1974).

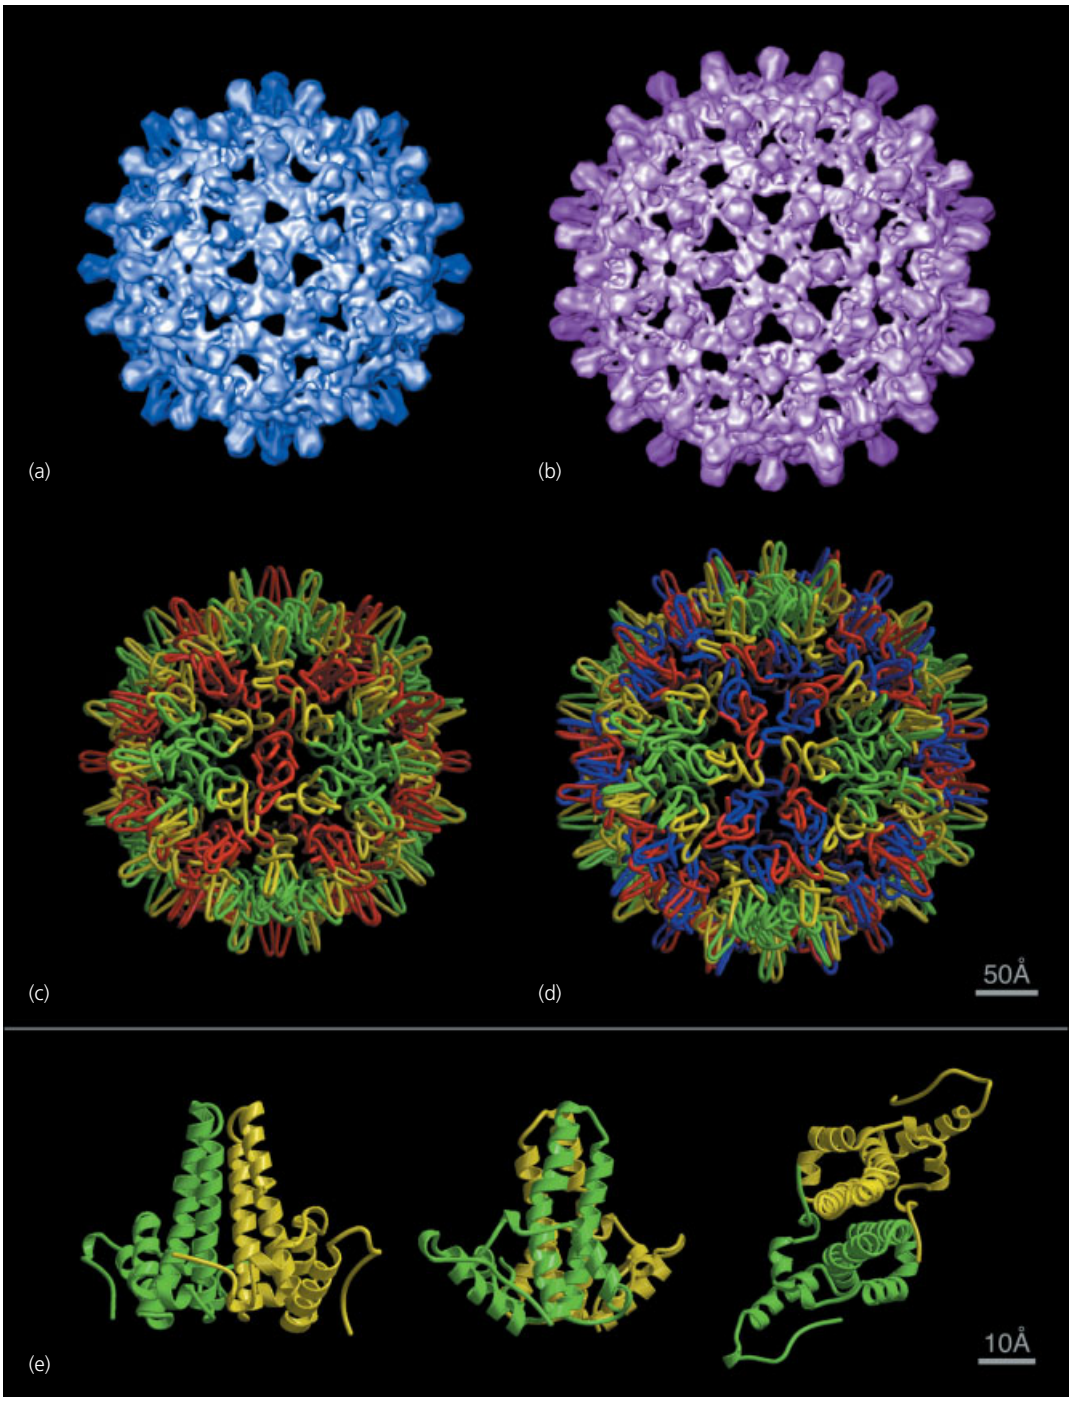

Figure 7 *Hepatitis B virus capsids come in two sizes: the smaller T = 3 capsid* **(a)** *and* **(c)** *with 180 subunits, and the larger T = 4 capsid* **(b)** *and* **(d)** *including 240 subunits. Surface views from cryo-EM reconstructions are shown in the top row at resolutions of 10 and 9 Å for* **(a)** *and* **(b)**, *respectively (Conway et al. 1997). The spikes rising from the capsid surface are four-helix bundles, with each of two capsid protein subunits contributing a helix–turn–helix motif to form a tight dimer interface. Unlike the SV40 and HK97 capsids of Figure 6, HBV does not have capsomers located on pentavalent and hexavalent sites, but instead the dimers cluster around these positions. The large holes in the capsid are presumably to allow nucleotides to diffuse inwards during reverse transcription of the RNA pregenome, following which the capsid will be enveloped on exiting from the host cell. The middle row shows tube renditions of atomic models of the capsids, based on the crystal structure of the T = 4 capsid (Wynne et al. 1999; PDB Id: 1QGT) but modified to fit the cryo-EM models (Watts et al. 2002). The monomer has three quasiequivalent positions in the T = 3 capsid* **(c)**, *color-coded as a green–yellow dimer and as a red–red dimer that lies on an icosahedral two-fold symmetry axis. For the T = 4 capsid* **(d)** *there are four different positions, coded as green–yellow and red–blue dimers. Views of a dimer are shown in* **(e)**, *where the four-helix bundle is evident. At left and center are two side views, and at right is a top view.*

Smaller capsids assemble around the viral genome or pregenome, whereas larger capsids are assembled first and then the genome is packaged through a specialized vertex, or portal. Packaging into a preformed capsid is driven by an ATP-dependent motor that works against a steadily increasing pressure gradient as the capsid fills. For dsDNA phages such as λ and HK97, the onset of packaging triggers a large-scale irreversible rearrangement of the capsid protein subunits, termed expansion (Figure 6b,c). For HK97 this trigger is proposed to be the repulsive force between the incoming DNA and the net negatively charged interior surface of the capsid (Conway et al. 2001). As a consequence of expansion, the HK97 subunits are displaced outwardly by 40 Å and rotate by 40° on average, and the internal volume doubles. Even with this additional volume to fill, the DNA is at high concentrations in these particles, of the order of 500 mg/ml. The capsid, which is round in the precursor form and highly contoured with protruding hexameric and pentameric capsomers, becomes planar and thin walled after expansion. Despite this thinning of the capsid wall, the buried surface area between subunits is estimated to be ~50 percent greater after expansion than before, suggesting that the larger subunit interfaces confer additional stability on the capsid, allowing it to withstand both the internal pressure of the packaged genome and external environmental stress.

Although this expansion transition is common among dsDNA phages, not all capsids that undergo a maturational reshaping necessarily expand. Recent work on HSV capsids indicates a number of conformational rearrangements, which serve to enhance contacts between subunits by closing gaps in the capsid, but with no significant change in its internal volume (Heymann et al. 2003). Another example is Nudaurelia capensis omega virus, a nonenveloped T = 4 RNA virus that infects insects, from which precursor virus-like particles are 16 percent larger than the mature virus, suggesting a maturational shrinkage (Canady et al. 2000). Large-scale structural rearrangements have not been seen in the assembly pathways of other icosahedral RNA viruses, although some plant viruses are observed to have a pH-dependent swollen state that is considered to be a disassembly transition during infection, much as is seen for poliovirus and other picornaviruses as a consequence of receptor binding (Fricks and Hogle 1990; Belnap et al. 2000; Hewat et al. 2002).

Tailed phages often bind one or more accessory proteins to the exterior surface of the capsid after expansion that confer additional stability. Trimers of the viral gpD protein bind to sites of local threefold symmetry on the surface of the T = 7 phage λ capsid, and these are essential for withstanding the internal pressure of packaging the full-length genome (Sternberg and Weisberg 1977). Phage T4 similarly binds the small outer capsid (Soc) protein at most local threefold sites, although it does not form a tight trimeric molecule (Iwasaki et al. 2000; Olson et al. 2001) as does λ's gpD (Yang et al. 2000). T4 also binds a second accessory protein (highly antigenic outer capsid (Hoc)), which populates local sixfold symmetry positions as a monomer (Iwasaki et al. 2000; Olson et al. 2001) but whose role is unknown. Somewhat akin to both Soc and Hoc is the vp26 protein of herpesvirus, which is dispensable for capsid formation and binds to the tips of hexamers of the major capsid protein vp5, but not to pentamers (Booy et al. 1994). The function of vp26 is unknown. Given its location, it may be expected to interact with a nonsymmetric protein layer called tegument that is between the capsid and the viral envelope (Trus et al. 1999), but this is not supported experimentally (Chen et al. 2001a). Phages HK97 and (probably) HK022 follow a different strategy to that of stabilizing the expanded capsid with accessory proteins. Covalent crosslinks between capsid proteins form autocatalytically as a consequence of expansion (Duda et al. 1995), generating a highly robust shell of interlinked protein rings (Duda 1998; Wikoff et al. 2000). This strategy of rigidifying the capsid is only feasible when the genome is to be released through a prebuilt channel, such as the connector-tail complex, rather than by capsid disassembly.

Different species, similar structures

Several observations of conserved architecture between viruses from quite different sources suggest far-reaching evolutionary relationships. The common features may be at the level of the capsid protein fold, as in the eight-strand β-barrel visualized in bacteriophages, plant, insect, and animal viruses (see Icosahedral capsid protein folds), to the larger-scale morphology of capsid geometry, including the recent intriguing identification of a special DNA packaging vertex on the HSV capsid that is reminiscent of the phage connector (Newcomb et al. 2001). For HSV the parallels with bacteriophages, particularly T4, have been drawn before. Common features include scaffold-assisted assembly, virus-encoded protease to process the immature capsid, maturational reorganization, the binding of accessory proteins, and the passage of the viral genome through a specialized vertex. There are, of course, important differences: the T4 tail, the HSV tegumentation and membrane, different proteins for hexameric and pentameric capsomers in T4, and so on. Possibly the similarities at the gross morphological scale are the results of convergent solutions to similar problems that the viruses face in packaging and delivering their genomes to new host cells. However, in another example, that of adenovirus and phage PRD1, the similarities on the gross scale are matched at the atomic level (Figure 8). Both viruses are unusual in the trimeric organization of their major capsid protein at hexavalent positions on a T=25 lattice, and they both employ a different protein for the

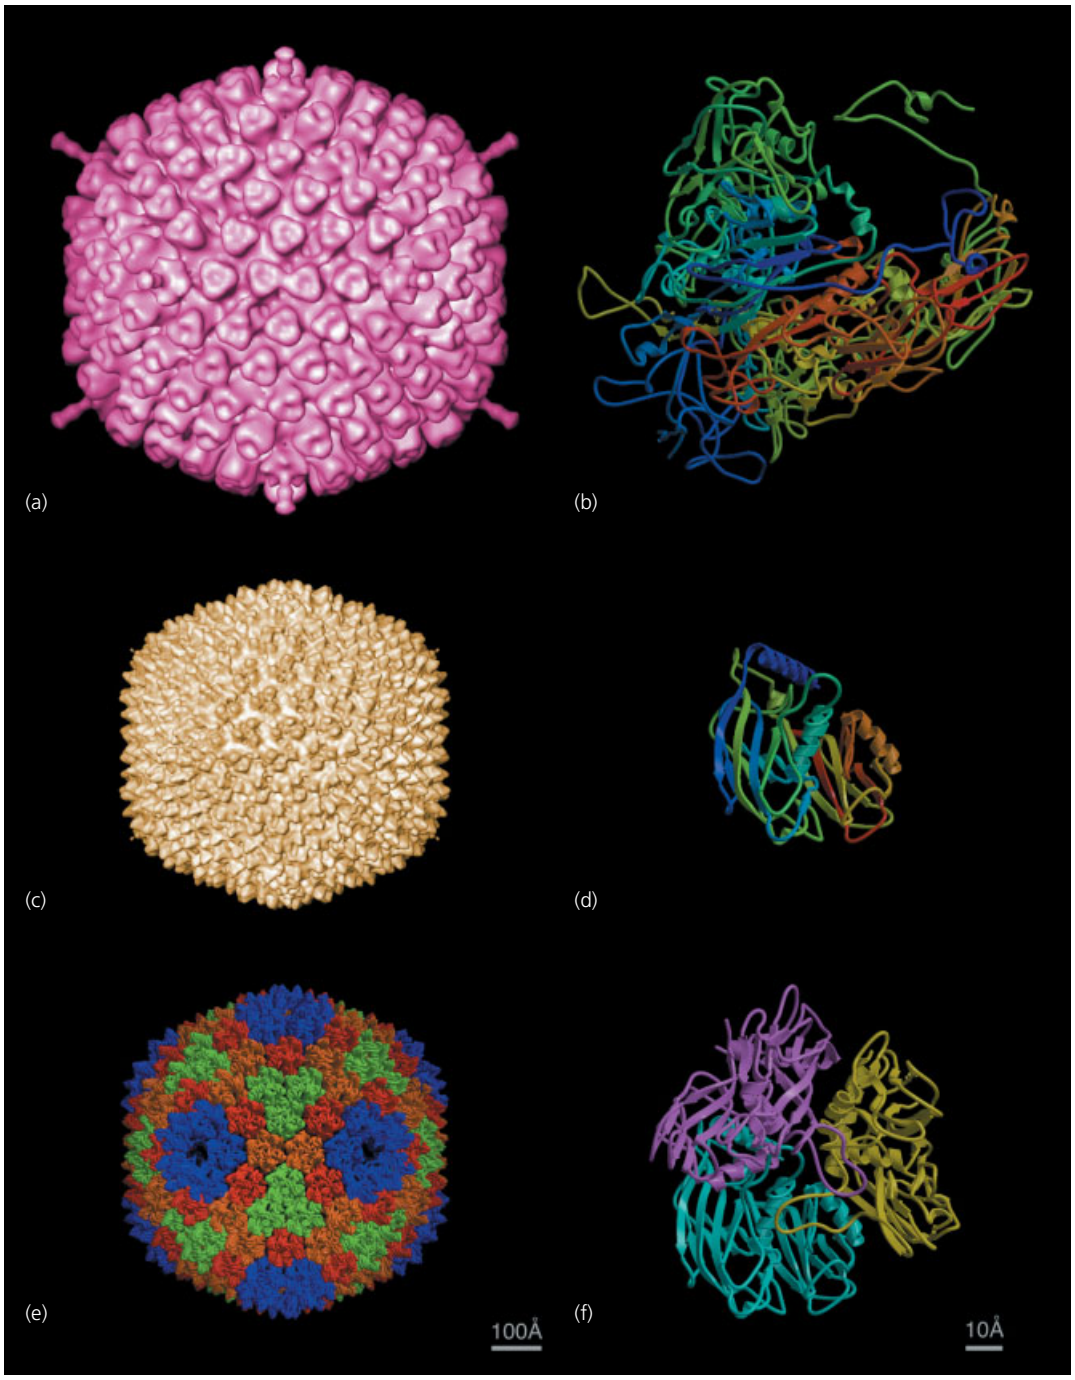

Figure 8 *Comparison of capsids from the mammalian adenovirus and bacteriophage PRD1. Despite differences in host-cell types, adenovirus and PRD1 share important structural similarities. Surface views of capsids from cryo-EM reconstructions are shown in panel* **(a)**, *adenovirus 2 at 25 Å resolution (Stewart et al. 1993; EMDS accession code 1016 – note that full icosahedral symmetry was not evident in the online density map, but has been imposed on the structure viewed here), and panel* **(c)**, *PRD1 at 16 Å resolution (San Martin et al. 2002; EMDS accession code 1011). These show the trimeric clustering of subunits on a T = 25 lattice. The adenovirus hexon trimers appear to have considerably more bulk than those of PRD1, which is a smaller capsid that also encloses a membrane. Trimeric spikes are partially visualized in the adenovirus structure, but not in that of PRD1. Atomic models of the major capsid proteins, colored from blue at the amino termini to red at the carboxy termini, are shown in panel* **(b)** *adenovirus hexon (Athappilly et al. 1994; PDB Id: 1DHX), and panel* **(d)** *PRD1 P3 protein (Benson et al. 2002; PDB Id: 1GW7). The adenovirus hexon is considerably larger (967 amino acids) than the PRD1 P3 protein (394 residues), with additional loops that extend upwards, but the core β-barrel is similar. An atomic model of the capsid, built from trimers of P3, is shown in panel* **(e)**, *where four adjacent trimers comprising the asymmetric units are colored purple, orange, red, and green. No structures are available yet for the pentameric vertex proteins, which are missing from this image. A single trimer of P3 is rendered as a ribbon diagram in panel* **(f)**.

pentameric vertices. Also in common is the binding of their receptor recognition molecule, a trimeric fiber, to the respective vertex pentons. The recent crystallographic structure of the PRD1 major capsid protein (Benson et al. 1999) has revealed a fold that is largely identical to that of the equivalent 'hexon' protein of adenovirus, with the exception of the protruding upper domain that is missing in PRD1. This remarkable set of similarities at all levels of structural detail suggests a common ancestry for these two virus proteins, which is further reinforced by a similar protein-primed mechanism of DNA replication initiation (Caldentey et al. 1992). Nonetheless, and not surprisingly, several striking differences are evident between these viruses, in particular the incorporation of a lipid bilayer on the interior of the PRD1 capsid and within which the viral DNA is enclosed. Structural comparisons of other important components, such as the pentameric vertex and trimeric fiber proteins, will be interesting to make when possible. A recent addendum to this fascinating story is the structural analysis of a large algal virus, PBCV1. This virus also incorporates an internal membrane, as does PRD1, but with a diameter of 1900 Å and triangulation number T = 169 its capsid is immensely larger than those of PRD1 and adenovirus (Yan et al. 2000). Nonetheless, the outer surface at 27 Å resolution appears to be populated by trimeric knobs that resemble the adenovirus hexon, and the recently solved structure of its major capsid protein is similar to the PRD1/adenovirus hexon fold (Nandhagopal et al. 2002).

NONSYMMETRICAL VIRUSES

Nonsymmetrical viruses do not have unique structures and cannot be crystallized. As mentioned above, cryo-EM leads to images with rather low signal-to-noise ratios, which can, in principle, be raised by averaging many virus particles if these are identical and can be aligned with each other. This is not possible for viruses that do not have unique structures. For these viruses the negative-staining technique is still often used.

All nonsymmetrical viruses are RNA viruses that have lipid membranes with membrane-embedded glycoprotein spikes. In most cases these spikes are associated with special lipid structures, called rafts (for reviews see Simons and Ehehalt 2002; Schmitt and Lamb 2004; Briggs et al. 2003). Lipid rafts are rich in cholesterol and sphingolipids and are not soluble in Triton X-100 or CHAPS at 4°C (London and Brown 2000), hence their alternative name: detergent-resistant membranes (DRM). The glycoprotein spikes associate with the lipid rafts during maturation in the Golgi apparatus and are transported in the membrane domains to the cell surface. The nonsymmetrical viruses usually also have a small matrix protein (20–30 kDa) that associates with the rafts and the cytoplasmic tails of the membrane-embedded glycoproteins and polymerizes at the interior of the membrane, bringing the rafts together and excluding cellular membrane-embedded proteins. The (encapsidated) genome binds to the layer of matrix protein to form an infectious virus particle. It seems that for the majority of nonsymmetrical viruses, much of the energy for building and maintaining the structure of the virus particle is due to these various and extensive interactions between membranes and proteins.

The glycoproteins are necessary for receptor binding, membrane fusion and, in some cases, for destroying the cell-surface receptors for release of newly formed virus from the infected cell (for those viruses that use sialic acid as receptor, such as influenza and parainfluenza viruses). The proteins that are active in fusion need to undergo a conformational change during which membrane fusion takes place. The trigger for the conformational change can be either low pH, if the virus is internalized through endocytosis (influenza virus and rhabdoviruses), or the trigger can be binding to a virus-specific cell-surface receptor (HIV, paramyxoviruses). The only structures solved for native fusion proteins are those of the hemagglutinins (HA) of influenza A virus and influenza C virus (Wilson et al. 1981; Rosenthal et al. 1998) and that of the fusion protein of Newcastle disease virus (Chen et al. 2001b). There exist now many structures of fusion proteins that correspond to the state of the protein after the conformational change related to membrane fusion. All these structures consist of triple coiled coils with a second layer of helices outside the inner coil (Skehel and Wiley 1998). This probably means that the fusion mechanism for all these viruses is similar, and it may also indicate that the structures before the change have similar features. The only exception may be the fusion-related conformational change of the rhabdovirus glycoproteins. The conformational change of VSV and rabies virus G is reversible, and after the change the fusion peptide is not inserted into the viral membrane, as is the case for influenza virus HA (Gaudin et al. 1995b, 1999).

As mentioned above, there exist neither atomic structures nor 3D EM models for the nonsymmetrical viruses. However, many proteins from these viruses have been crystallized and their structures solved. Table 1 gives a list of these structures per virus family. For the retroviruses we have only given the structures of the HIV proteins, although many other protein structures are also known, for example those of SIV proteins.

Negative-strand RNA viruses

The viruses in this group have a genome in the opposite sense to that of mRNA, and for this reason transcription is the first event that takes place after the virus enters the cell. All these viruses have a nucleocapsid in which the viral RNA is tightly and stoichiometrically bound to a nucleoprotein. The interactions between the

nucleoprotein molecules determine the helical parameters of the nucleocapsid (Ruigrok and Baudin 1995); see Figure 9. They also have matrix proteins with affinities for lipid membranes and for nucleocapsids. All the matrix proteins have a tendency to polymerize, either into well-defined oligomers or into large polymers (Heggeness et al. 1982; Gaudin et al. 1995a, 1997; Ruigrok et al. 2000b; Baudin et al. 2001; Timmins et al. 2003). Polymerization of the matrix proteins probably pulls the glycoproteins in their lipid rafts together to form the virus particle. Interestingly, there are now three structures known of negative-strand RNA virus M proteins, from influenza virus, Ebola virus, and VSV (see Table 1), and all are different, suggesting that they are not evolutionarily related. Because the polymerization of the matrix proteins drives the assembly of the negative-strand RNA viruses, the existence of evolutionarily unrelated matrix proteins could imply that the blueprints of viruses from the various families are different.

ORTHOMYXOVIRUSES

We will use the influenza A virus to explain in detail the structure of negative-strand RNA viruses. A schematic

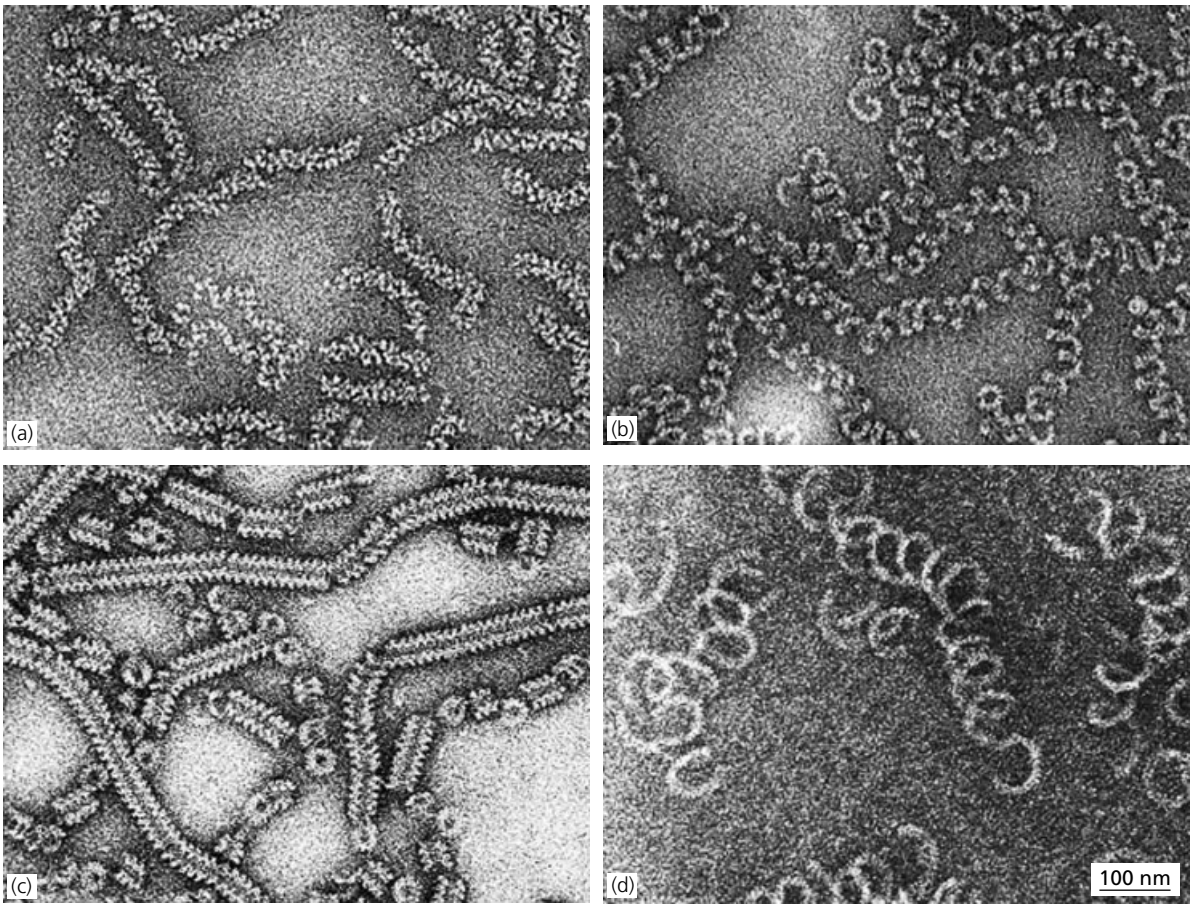

Figure 9 *Electron micrographs of negatively stained nucleocapsids of* **(a)** *influenza,* **(b)** *rabies,* **(c)** *measles, and* **(d)** *Marburg viruses. Scale bar = 100 nm.*

drawing of influenza A virus is shown in Figure 10 and various electron micrographs in Figure 11, p. 17. Influenza virus has a segmented RNA genome consisting of eight segments (seven for influenza C virus), each individually bound to a polymerase complex and each encapsidated by the nucleoprotein (Martín-Benito et al. 2001).

Transport component

Influenza virus has three transmembrane proteins: hemagglutinin (HA), neuraminidase (NA), and the M2 protein. HA is a homotrimer with a stalk part consisting of HA_2, which carries the membrane fusion activity, and a more globular head part made up by HA_1, which carries the receptor-binding function (Wilson et al. 1981; Skehel and Wiley 2000). NA forms tetramers and consists of a boxlike head that contains the enzymatic receptor-destroying activity, on a long and thin stalk (Varghese et al. 1983; Burmeister et al. 1992). M2 forms a tetrameric membrane channel (Sugrue and Hay 1991; Pinto et al. 1992; Shuck et al. 2000) that is needed for acidification of the interior of the virus as it passes through the endosomal system. Acidification is needed for depolymerization of the matrix protein so that the individual RNPs can enter the nucleus (Martin and Helenius 1991). Both HA and NA are embedded into lipid rafts, but M2 is not (Scheiffele et al. 1999; Ali et al. 2000; Zhang et al. 2000a, b; Barman et al. 2001).

Replication component

Each RNA segment is individually bound to a heterotrimeric polymerase complex and each is encapsidated by the nucleoprotein (Figure 9). The polymerase binds directly to the 3′ and 5′ ends of the RNA, and this complex RNA element forms the promoter for transcription and replication (Hagen et al., 1994; Cianci et al. 1995; Li et al. 2001). Martín-Benito et al. (2001) have made a 3D reconstruction from recombinant and short RNPs that lacked the extensive flexibility and diversity in shape of real viral RNP. The nucleoprotein molecules touch at one extreme side, as was already suggested from negatively stained nucleoprotein polymers (Ruigrok and Baudin 1995). Interestingly, the 3D model also shows extensive contacts between NP molecules and two of the polymerase subunits. Early work suggested that each NP monomer was associated with 20–26 nucleotides (nt) (Compans et al. 1972; Jennings

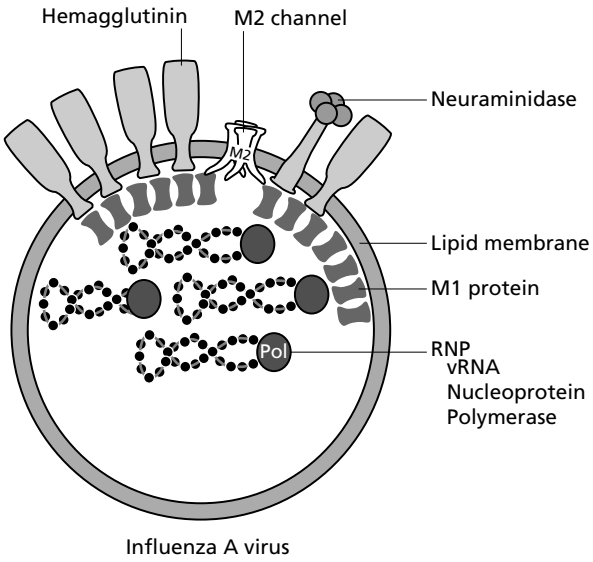

Figure 10 *Schematic drawing of an influenza A virus particle.*

et al. 1983). The same group that made the 3D EM reconstruction found that certain lengths of RNA produced recombinant RNP that replicated better than other lengths. These results suggested that the optimal unit of influenza virus RNA that can be encapsidated is not 24 nt per NP monomer, but 48 nt per NP dimer (Ortega et al. 2000). NP binds to the phosphate sugar backbone of the RNA in a sequence-nonspecific manner and, in doing so, prevents RNA secondary structure formation and exposes the nucleotide bases to the outside. In this way, the polymerase can probably read the vRNA without the need for dissociation of NP from the RNA (Baudin et al. 1994; Klumpp et al. 1997).

Connection between replication and transport components

The matrix protein (M1) binds the two components together in the virus particle. M1 consists of two domains, an N-terminal domain that has affinity for membranes and a C-terminal domain that has affinity for the RNP (Baudin et al. 2001). The affinity for membranes appears to be electrostatic and M1 in the virus does not seem to insert into the viral membrane (Ruigrok et al. 2000a). M1 binds to the cytoplasmic tails of the glycoproteins (Jin et al. 1997) and binds also to the M2 membrane channel (Zebedee and Lamb 1989). It is likely that the polymerization of M1 pulls together the fields of lipid rafts with their embedded glycoproteins, and that these fields are subsequently glued together through the M1–M2 interactions. If this model were correct, it would imply that the virus contains more or less rigid and curved protein-membrane sections stuck together at hinge points containing M2 protein. This kind of organization could explain some of the particle shapes of frozen hydrated virus (Figure 11a) and of virus negatively stained with tungstate salts such as sodium silicotungstate (SST) and phosphotungstate (PTA) (Figure 11c). A similar model has been proposed for immature HIV particles (Fuller et al. 1997). Such a model also implies that all particles will be slightly different in size and shape. Interestingly, there seem to be about as many copies of M1 protein in a virus particle as there are monomers of the glycoproteins (Ruigrok 1998).

Influenza B and C viruses

The overall shape of influenza B virus seems to be similar to that of the A virus, albeit more spherical than the ellipsoid A virus (Cusack et al. 1985). An interesting detail was observed for the structure of the influenza C virus glycoprotein (Rosenthal et al. 1998). This protein is a trimer of identical subunits. Each subunit consists of two parts (obtained after maturation cleavage by a host protease): a fibrous stalk containing the fusion activity and a more globular head domain carrying the receptor-binding activity, just as in influenza A virus HA (Wilson et al. 1981). However, the influenza C glycoprotein has an extra domain inserted into the receptor-binding domain. This extra domain contains the receptor-destroying activity, and as the influenza C virus does not have a special gene for this function it has not eight but seven gene segments (Compans et al. 1977; Herrler et al. 1981; Desselberger et al. 1980). This single influenza C virus glycoprotein can be organized into a hexagonal surface lattice (Flewett and Apostolov 1967). The influenza C virus glycoprotein is not associated with DRM (Zhang et al. 2000b). Apparently, the structure of the glycoproteins can accommodate additional domains and the different viruses can have their various functions associated with different glycoproteins.

PARAMYXOVIRUSES

The viruses in this large group are all spherical particles that easily deform when negatively stained for EM observation (Figure 12, p. 18). The main difference with the influenza viruses is that the genome is not segmented.

Transport component

The paramyxoviruses have trimeric fusion proteins that do not carry the receptor-binding function. This function is found on the H or HN (hemagglutinin–neuraminidase) protein, which has a similar shape to that of influenza virus neuraminidase. Those viruses that use sialic acid as receptor also have a sialidase with receptor-destroying function associated with the HN protein. However, those viruses that bind to other receptors, such as measles virus, do not have a receptor-destroying activity. The glycoproteins of the viruses in this group are also associated with lipid rafts (Manie et al. 2000; Brown et al. 2002; Henderson et al. 2002).

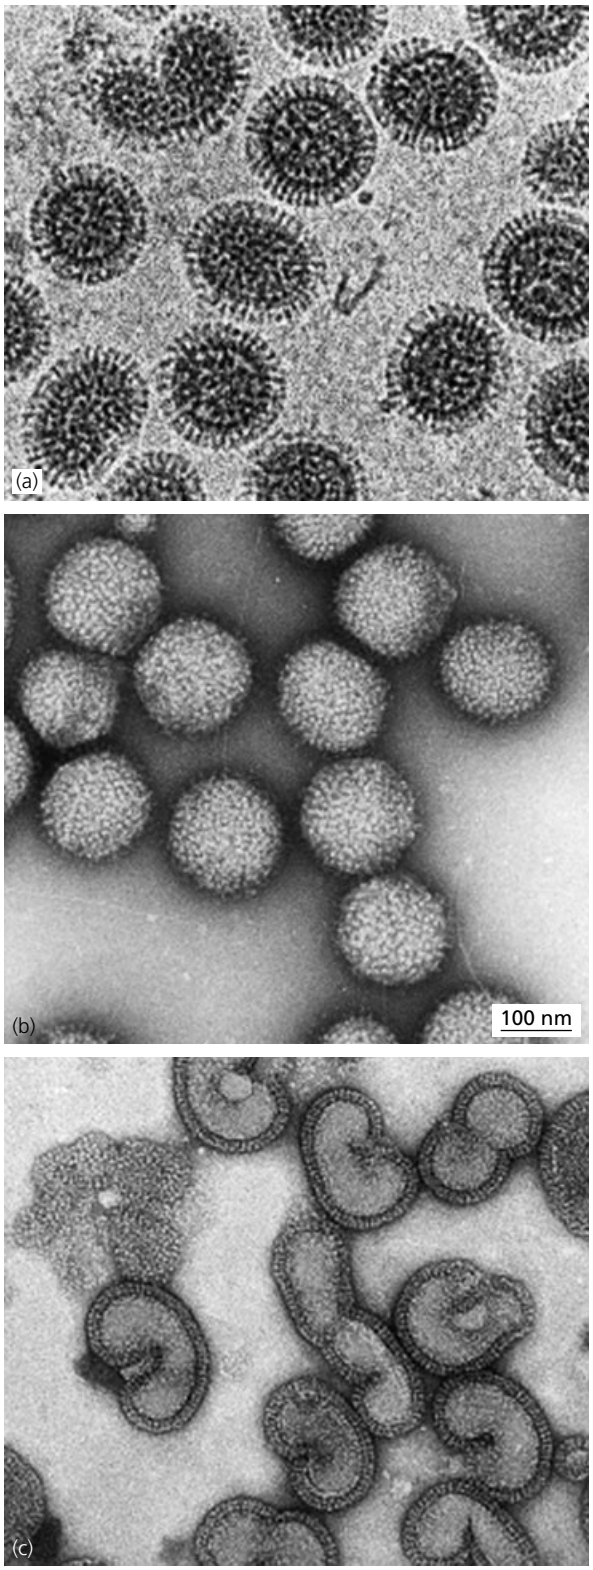

Figure 11 *Electron micrographs of influenza B virus (orthomyxoviruses prepared by* **(a)** *fast freezing (cryo-EM),* **(b)** *negative staining with 1% uranyl acetate, and* **(c)** *negative staining with 1% sodium silicotungstate. Scale bar = 100 nm.*

Replication component

The viral RNA is bound to the nucleoprotein with a stoichiometry of six nucleotides per nucleoprotein monomer (Egelman et al. 1989). This N-RNA forms the characteristic herringbone structure that is often used for the identification of paramyxoviruses (Figures 9 and 12). For some of the viruses in this group this stoichiometry even translates into a 'rule of six': these viruses must have a total number of nucleotides that is a multiple of six (Calain and Roux 1993; Kolakofsky et al. 1998). The proper positioning of the nucleoprotein on to the RNA has an influence on how the polymerase reads the various transcription signals, i.e. on how the polymerase recognizes the nucleotide bases (Iseni et al. 2002). The helical parameters for the nucleocapsids (NC) of the different viruses in this group are not the same: Sendai virus and measles virus have about 13 subunits per helical turn; simian parainfluenza virus 5 (SV-5) NC have 14 subunits; and respiratory syncytial virus (RSV) nucleocapsids contain predominantly ten subunits (Bhella et al. 2002).

The paramyxovirus polymerase is a monomer with polymerase activity that also produces a 5′ cap structure plus the poly-A tail of the viral mRNA. The polymerase is fixed on to the N-RNA template by a tetrameric phosphoprotein (Tarbouriech et al. 2000). The phosphoprotein binds with its C-terminal domain to the C-terminal domain of the nucleoprotein, and the polymerase binds to the oligomerization domain of the phosphoprotein (Curran et al. 1995).

Connection between replication and transport components

As with the influenza viruses, the viral matrix protein makes the connection between the membrane with its embedded spikes and the replication component. Isolated M polymerizes into helical structures depending on the salt concentration (Hewitt and Nermut 1977) and forms orthogonal arrays at the inside of the viral membrane and at the inside of the plasma membrane of infected cells (Büechi and Bächi 1982). The nucleocapsid packs against these arrays to form new virus particles.

RHABDOVIRUSES

This family contains two major groups of bullet-shaped viruses (Figure 13), the vesiculoviruses and the lyssaviruses. The viruses in these groups have similar structures, although there are also differences.

Transport component

These viruses have a single, trimeric glycoprotein G that contains the receptor-binding and the fusion activities. The viruses do not have a receptor-destroying activity. Although Brown and Lyles (2003) show interaction of

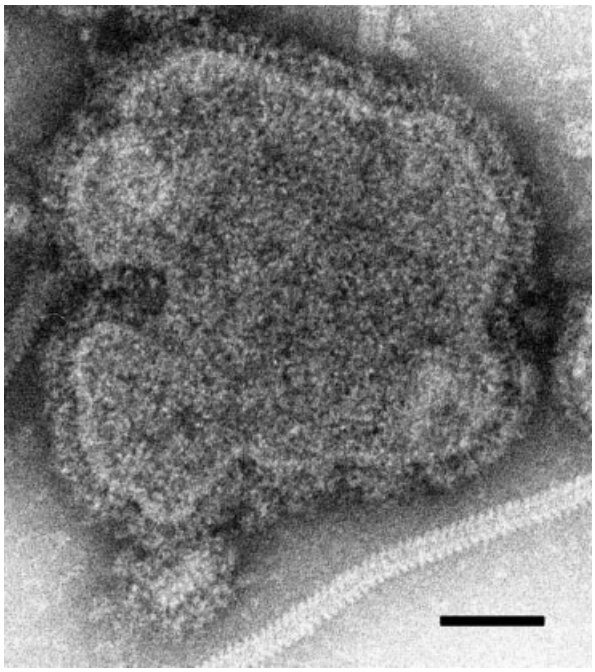

Figure 12 *Electron micrograph of measles virus (paramyxoviruses) negatively stained with 1% sodium silicotungstate. Note the helical nucleocapsid in the background. The bar corresponds to 100 nm.*

VSV G with membrane microdomains, there is still debate about whether or not the protein is associated with DRM (discussed in Briggs et al. 2003). It is possible that the membrane domains with which G associates do not have the same structure and composition as detergent-resistant membranes (Owens and Rose 1993; Johnson et al. 1998). For rabies virus, there is also no proof for DRM association from detergent resistance and membrane-floatation experiments (Y. Gaudin, personal communication). The trimeric nature of the rabies virus glycoprotein is clearly visible on EM under slightly acidic conditions (Gaudin et al. 1992). Under these conditions G can also self-associate to form a honeycomb structure, thought to be an intermediate for membrane fusion (Gaudin et al. 1996). Trimerization of the glycoprotein of VSV is also considerably more stable at low pH (Doms et al. 1987).

Replication component

The NC of rabies virus and VSV are loose coils (Figure 9) where each N monomer is bound to nine nucleotides (Thomas et al. 1985; Iseni et al. 1998). As for influenza virus and Sendai virus, the nucleoprotein is bound to the sugar phosphate backbone of the RNA and the nucleotide bases are exposed to the outside (Iseni et al. 2000). The polymerase is bound to the N-RNA by the phosphoprotein, which is also an oligomer, but the exact oligomeric state has not yet been clarified (Gigant et al. 2000).

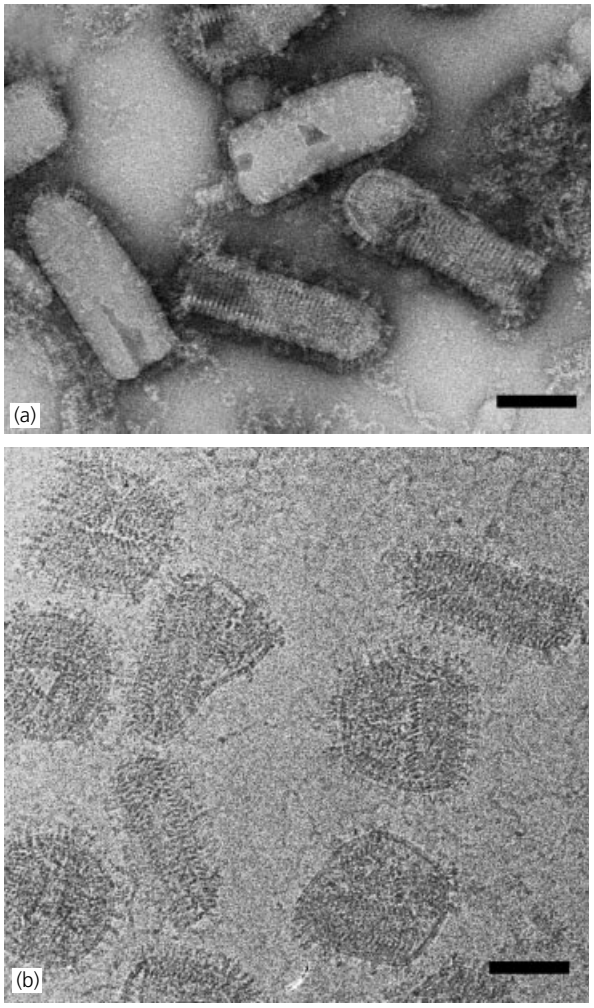

Figure 13 *Electron micrographs of VSV (rhabdoviruses) prepared by* **(a)** *negative staining with 1% sodium silicotungstate and* **(b)** *fast freezing (cryo-EM). Note in* **(b)** *that the nucleocapsid is sometimes doubled up to form a more spherical particle. The bar corresponds to 100 nm.*

Connection between replication and transport components

The formation of rhabdovirus particles is different from that of the myxoviruses described above. The viral matrix protein associates with the nucleocapsid in the cytoplasm and forms a tightly coiled M–NC complex (Newcomb and Brown 1981; Newcomb et al. 1982; Odenwald et al. 1986). There is a significant increase in the diameter of the helical nucleocapsid upon association with M, owing to slight changes in the angle between N subunits and the tilt angle with respect to the helical axis (Schoehn et al. 2001). The M–NC complex then binds to the cell membrane and, while pushing through it, associates with the glycoprotein spikes (Odenwald et al. 1986). The exact structure of the M–NC complex and the position of the matrix protein is not known. For VSV it has been observed that there is

mass inside the nucleocapsid coil, and it has been proposed that at least some of the matrix protein forms a scaffold around which the nucleocapsid is coiled (Brown and Newcomb 1987; Barge et al. 1993). However, this hypothesis on the positioning of the matrix protein is contested by claims that all of M is in contact with the membrane (Chong and Rose 1993). In any case, in contrast to the viruses described above, where the polymerization of the matrix protein leads to membrane curvature and particle shape, for the rhabdoviruses it is the preformed M–NC structure that gives the bullet shape to the rhabdovirus particles.

The VSV particle contains some 1 200 monomers of G, 1 260 monomers of N, and 1 800 monomers of M (Thomas et al. 1985). The rabies virus particle contains much less M – only about 700 copies – whereas it was estimated that there are as many N as G monomers, i.e. some 1 330 copies (Dietzschold et al. 1979; Flamand et al. 1993). Therefore, it would be possible that, in rhabdoviral particles, G associates with N rather than with M. The difference in M protein content between rabies and VSV could mean that there is a difference in structure between the two viruses.

FILOVIRUSES

Filoviruses are long and thin (Figure 14), much longer than rhabdoviruses (Feldmann and Klenk 1996; Feldmann and Kiley 1998). There are two groups of filoviruses, Ebola and Marburg. Although many different shapes, such as comma and laureate, have been described, only long and nonbranched particles are seen budding from infected cells (Feldman and Klenk 1996). Because of the high pathogenicity of the virus, only extensively fixed infected cells or purified virus have been used for electron microscopy.

Transport component

The filoviruses have a single glycoprotein with receptor-binding and membrane-fusion activity. This protein is associated with lipid rafts (Bavari et al. 2002).

Replication component

The image of the isolated nucleocapsids in Figure 9 was made from nucleoprotein expressed in insect cells. This protein binds to cellular RNA with a stoichiometry of about one N monomer per 12 or 15 nucleotides (Mavrakis et al. 2002). The shape of the N monomers looks somewhat like that of rhabdovirus N, as does the overall appearance of the N RNA. Apart from the nucleoprotein, the polymerase and the phosphoprotein (probably VP35), there is a fourth protein associated with the nucleocapsid of filoviruses, the VP30 protein (Becker et al. 1998; Modrof et al. 2001).

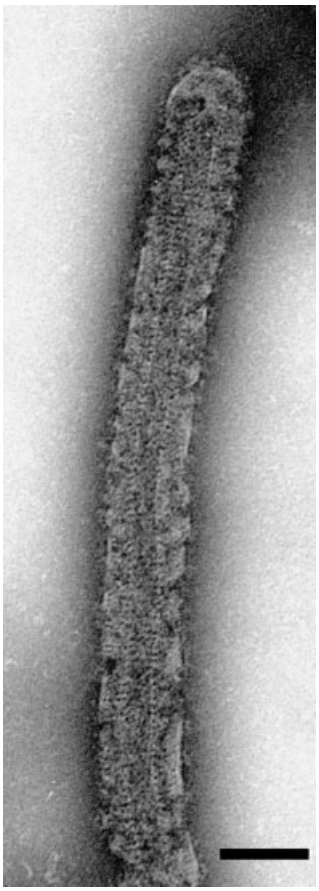

Figure 14 *Electron micrograph of an extensively fixed Marburg virus particle (filoviruses) negatively stained with 1% uranyl acetate. The bar corresponds to 100 nm.*

Connection between replication and transport components

The filoviruses have two matrix proteins, VP40 and VP24. VP40 is a two-domain protein (Dessen et al. 2000). The two domains can be dissociated by mutations that destabilize the domain interface, by treatment with low concentrations of urea or by putting the protein in contact with negatively charged lipid membranes (Ruigrok et al. 2000b). When the domains separate, the N-terminal domain associates into ringlike structures and the C-terminal domain binds to membranes (Ruigrok et al. 2000b; Timmins et al. 2003). It is thought that such a conformational change is needed for binding of VP40 to the cell membrane to start particle formation. The diameter of the free Marburg virus nucleocapsid is about 40 nm, whereas the diameter of this structure inside the virus is only 27 nm (Mavrakis et al. 2002). Therefore, whereas the coil diameter of the rhabdovirus nucleocapsid increases as it condenses into the M–NC complex, reducing the length of the structure, for filoviruses the NC diameter decreases, leading to an increase in length. This may be the reason why filoviruses are so long. The *Filovirus* nucleocapsid is also condensed in the cytoplasm, like that of the

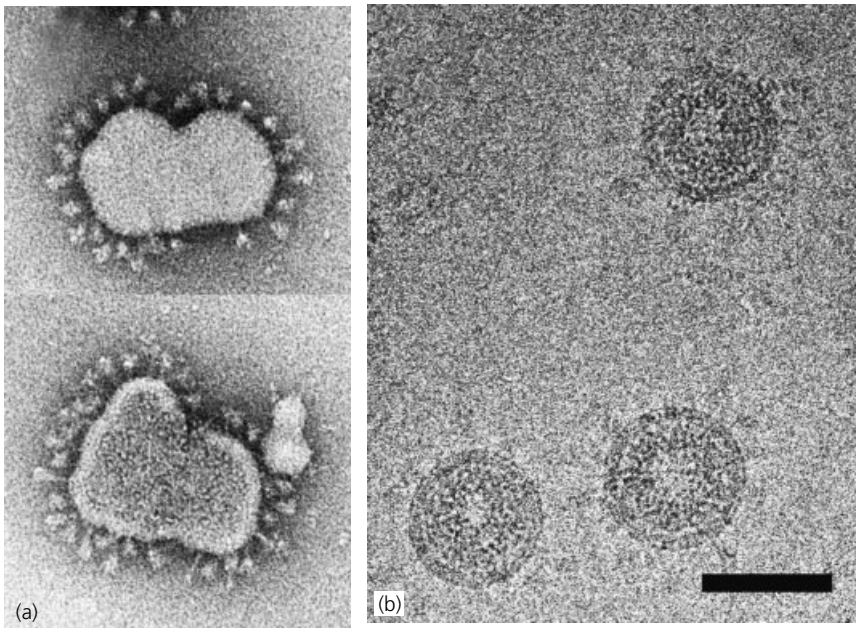

Figure 15 *Electron micrographs of Porcine respiratory coronavirus (PRCV) after* **(a)** *negative staining with 1 percent sodium silicotungstate, and* **(b)** *fast freezing (cryo-EM). Note the petalshaped spikes in* **(a)** *and the spherical shape of the particles in* **(b)**. *The bar corresponds to 100 nm.*

rhabdoviruses, before it goes into the virus particle (Kolesnikova et al. 2000), and it also seems to be this preformed structure that gives the shape to the virus particle. Between the nucleocapsid and the viral membrane there is an extensive and regular network or scaffold of proteins (Mavrakis et al. 2002; see Figure 14). This network is probably made up by the VP40 rings, with or without a contribution of VP24.

CORONAVIRUSES

The coronaviruses, together with the toroviruses and the arteriviruses, form the order of the *Nidovirales*.

Transport component

The name of this group of viruses is derived from its image in negative-stain EM of a spherical particle crowned with petalshaped glycoproteins spikes (S) (Figure 15a). S is a trimer (Delmas and Laude 1990).
There are two major subgroups of mammalian coronavirus. It seems that S of viruses of subgroup II is cleaved into two parts (like influenza virus HA) and that the trigger for fusion is low pH; and that S of subgroup I viruses is not cleaved and that fusion takes place at neutral pH after interaction with a specific receptor (Hansen et al. 1998; Zelus et al. 2003). However, Gallagher et al. (1991) have isolated different mutants from the same strain of murine hepatitis virus type 4 (group II) with very different pH requirements for fusion, with only a limited number of amino acid substitutions between the mutants. It is possible that the conformational changes that accompany fusion for the *Coronavirus* S glycoprotein are similar to those of the majority of other viral fusion proteins, because the predicted secondary structure of S also shows two amphiphylic helices per monomer (de Groot et al. 1987; Bosch et al. 2003). The terminal S1 domain is involved in receptor binding (Suzuki and Taguchi 1996), whereas the S2 subunit is involved in membrane fusion (de Groot et al. 1989; Yoo et al. 1991). The *Coronavirus* membrane has at least one other glycoprotein embedded: the small M protein that traverses the membrane three times (Machamer and Rose 1987). For the arteriviruses it has been shown that the membrane can contain several other minor proteins (hemagglutinin esterase (HE), small envelope protein (E), GP(3), and GP(4); Wieringa et al. 2002). It is not known yet whether the coronavirus surface glycoproteins are associated with membrane rafts.

Replication component

Coronaviruses are positive-strand RNA viruses with large genomes of between 27 and 32 kb. This genome size is one of the reasons for the high production of mutant viruses. The viral RNA is capped and polyadenylated (Schochetman et al. 1977; Lomniczi 1977), and upon cell entry the first open reading frame coding for the polymerase is translated. The polymerase then produces subgenomic (sg) copies of the RNA that code for the rest of the viral proteins (Lai and Cavanagh, 1997; van Marle et al. 1999; van Vliet et al. 2002).

Connection between replication and transport components

There is a disagreement in the literature about the function and position of the internal 'nucleocapsid protein' (N). For the arteriviruses it is assumed that N forms a spherical (icosahedral?) shell around the viral RNA. However, no icosahedral reconstructions of these viruses exist, and electron micrographs of thin-sectioned virus particles do not show spherical but rather ellipsoid shapes (Brinton 1999), thereby throwing doubt on the existence of icosahedral symmetry. Older literature on coronaviruses describes N forming helical complexes with vRNA (Macnaughton et al. 1978; Davies et al. 1981) and, because of its positively charged nature, N has been compared with influenza virus nucleoprotein (Laude and Masters 1995). Later work on coronaviruses has suggested that N forms a spherical structure beneath the viral membrane, and that maturation of this structure takes place upon transport of the virus towards the outside of the cell (Risco et al. 1998; Salanueva et al. 1999). The diameter of coronaviruses embedded in vitreous ice is very variable, with no specific size classes (Schoehn, unpublished results), suggesting that the virus does not have icosahedral symmetry.

A number of the characteristics of *Coronavirus* N correspond also to those of the matrix proteins of the negative strand RNA viruses that are also strongly positively charged.

- *Coronavirus* N does not only bind to RNA but also to lipid membranes (Stohlman et al. 1983), a property shared with the positively charged M1 protein of influenza virus that binds to membranes and to naked nucleic acids (Baudin et al. 2001).
- *Coronavirus* N has a tendency to form trimeric complexes (Laude and Masters 1995), a property shared with the MA protein of the retroviruses.
- Detergent-treated influenza virus particles also release helical structures that were initially interpreted to be formed of ribonucleoprotein but which are now thought to consist of oligomeric M1 complexes (Murti et al., 1980, 1992; Ruigrok et al., 1989).
- Experiments with plasmid-expressed proteins suggest that the viral glycoproteins alone can form VLP and leave the cell, but N expressed alone can also form VLP (Vennema et al. 1996), like the matrix proteins of negative-strand RNA viruses and retroviruses.

We only make these comments in order to indicate that, in our opinion, the fine structure of coronaviruses is not yet known in detail.

RETROVIRUSES

As a group, retroviruses are perhaps as variable as the negative-strand RNA viruses. This part of the review will discuss the general principles of retrovirus structures; for more detailed information the reader is referred to Goff (2001) and subsequent chapters in *Fields' Virology*. The structures of virtually all HIV proteins (Table 1) and many proteins of other retroviruses have been determined by either crystallography or NMR, but no intact virus or capsid structure has been determined because of a lack of defined symmetry.

Transport component

Retroviruses have a single trimeric glycoprotein (GP160) that, at least for HIV, is associated with lipid rafts (Manes et al. 2000; Ono and Freed 2001) (see Figure 16 for a negatively stained SIV particle showing end-on views of the triangular spikes). As for influenza virus HA, GP160 is posttranslationally cleaved into two parts: N-terminal GP120, which is responsible for binding to primary and secondary receptors, and C-terminal GP41, which is membrane anchored and responsible for membrane fusion. GP120 is placed upon GP41, much like the organization of influenza virus HA. GP41 has the same triple coiled coil structure as the fusion proteins of the segmented and nonsegmented negative-strand RNA viruses, implying that the fusion proteins are evolution related and that the fusion processes of all these viruses follow the same mechanism.

Replication component

The replication component of retroviruses consists of the viral RNA bound to the nucleocapsid (NC) protein plus copies of the reverse transcriptase and integrase (see below), necessary for the production of retrotranscribed viral DNA and its integration into the host genome. NC forms a complex with vRNA and facilitates annealing of vRNA with the tRNA primer for reverse transcription (Barat et al. 1993), and prevents the reverse transcriptase stopping at stable stem-loops in the RNA (Wu et al. 1996). In this respect NC has

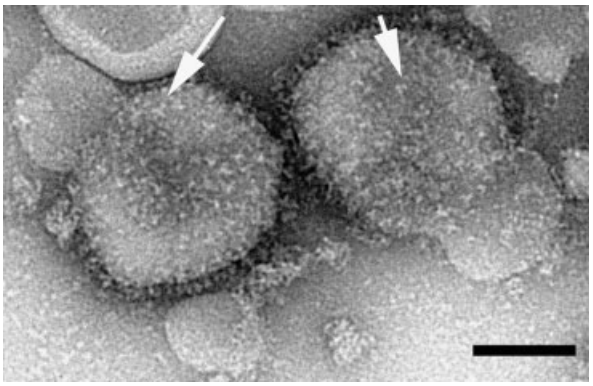

Figure 16 *Electron micrograph of simian immunodeficiency virus (SIV, retroviruses) particles negatively stained with 1% uranyl acetate. The arrowheads point out triangular shapes of the trimeric surface glycoprotein. The bar corresponds to 100 nm.*

been named an RNA chaperone (Feng et al. 1999). Although probably structurally different, the function of the retroviral NC protein may be similar to that of the negative strand RNA virus nucleoprotein (see above).

Virus assembly and maturation

The most simple retroviruses code for two polyproteins, Gag and Pol, and a small percentage (about 10 percent) of Gag–Pol proteins when the ribosome reads through the stop codon or when a frame shift occurs at the Gag–Pol boundary, depending on the virus family. More complex viruses have a series of smaller proteins that modulate cellular processes (Goff 2001). The Gag polyprotein consists of the matrix (MA), capsid (CA), and the NC proteins, and Pol consists of the protease (PR), integrase (IN), and the reverse transcriptase (RT). The structure of immature virus was studied from Gag expressed in insect cells or bacteria, which forms virus-like particles (VLP) (Nermut et al. 1994, 2002; Fuller et al. 1997), and from virus with a mutated and inactive protease (Stewart et al. 1990). In immature virus or VLP Gag binds to membranes through the matrix protein (see Figure 17) and it forms locally ordered hexagonal lattices (Nermut et al., 1994, 2002; Yeager et al. 1998; Forster et al. 2000; Mayo et al. 2003). However, the spherical structures that are formed are not icosahedral (Fuller et al. 1997; Yeager et al. 1998). Rather, it appears that the Gag polymers bind to membrane patches, leading to shells with local curvature. Somehow, these shells are then joined to form VLP with various diameters (Fuller et al. 1997). The presence of local organization of Gag and curved membrane elements could be similar to what is observed for influenza viruses, where curved M1 membrane shells may be joined by the transmembrane M2 protein (see above). The Gag–Pol proteins are included in the viral bud because the Gag of the Gag–Pol polymerizes with the rest of Gag into the virus. Inside the Gag polymer, nucleic acid (random for recombinant VLP and viral RNA for intact or PR virus) is bound to the NC part of Gag.

When the virus has budded from the plasma membrane and left the cell, the protease cleaves Gag into MA, CA, and NC, and Pol into PR, IN, and RT. NC remains associated with the viral RNA, MA remains at the membrane and there is no indication that it rearranges at the membrane, but CA forms a new structure inside the virus particle, the capsid (Figures 17 and 5.18). The capsid is a closed structure for all the retroviruses, but its form differs by family. As described above for the icosahedral viruses, closed capsids may consist of 12 pentavalent capsomers and a variable number of hexavalent capsomers. The retroviral capsid is also built from CA monomers that are organized into 12 pentavalent and a variable amount of hexavalent units. However, the pentavalent units can be placed at various positions (Ganser et al. 1999; Li et al. 2000). If six pentavalent units are placed close together at one end, six at the opposite end and the rest of the structure consists of hexavalent units, a hollow tube is formed that is indeed sometimes observed in structures formed by purified CA protein in vitro, and which are also observed inside mature HIV (Li et al. 2000; Briggs et al. 2003). Other conical forms are made when the pentavalent units are distributed in an unequal fashion, with five at one end and seven at the other, or other variations (Ganser et al. 1999). All these forms are observed in mature HIV (Briggs et al. 2003). Other retroviruses, such as murine leukemia virus, form rather spherical capsids with a more equal distribution of the pentavalent

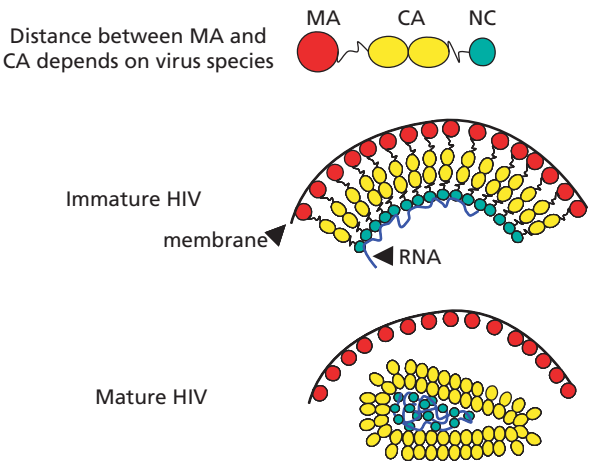

Figure 17 *Schematic representation of the changes in HIV capsid structure upon maturation.*

Cryo-electron microscopy reveals ordered domains in the immature HIV-1 particle. Current Biology, Vol. 7, pp. 729–38. Copyright (1997), with permission from Elsevier.*

units on a spherical surface, but these capsids are also not all identical and are not icosahedral (Yeager et al. 1998; Kingston et al. 2001). Another observation which goes against the idea that retroviruses have icosahedral structures is that mature and immature viruses do not have diameters with defined values but with rather wide distributions (Fuller et al. 1997; Yeager et al. 1998; Kingston et al. 2001; Briggs et al. 2003). This size variation suggests that smaller viruses can include less nucleic acid than larger viruses, and for HIV it was indeed found that the larger viruses had more than one capsid cone (Briggs et al. 2003).

Some retroviruses do not assemble at the cell membrane but form an immature Gag sphere in the cytoplasm, which subsequently associates with the membrane and the glycoproteins. One could imagine that these viruses are icosahedral, but careful analysis of many different retrovirus families has failed to reveal icosahedral symmetry (S.D. Fuller, personal communication). Another indication that the structures of viruses that assemble at the plasma membrane and those that assemble in the cytoplasm are not essentially different is that a single mutation in MA can change a virus that normally assembles in the cytoplasm into a membrane assembler (Rhee and Hunter 1990).

FINAL COMMENTS

This chapter on virus structures is necessarily incomplete owing to the vastness of the topic. One may look into *Fields' Virology* or similar monumental tomes for additional information. Viruses and virus families may not have been treated here, mainly because none of the authors has worked with them: for example, the nonsymmetrical negative-strand RNA bunya and arenaviruses. However, what has become clear to us during writing this text is that even viruses of the same family can show significant differences in structure, and recent studies also demonstrate that structure may be shared between apparently distant families. We expect that the continuing development of biophysical techniques, especially X-ray crystallography and electron microscopy, will continue to play an important role in defining more details about virus morphology and connecting that information to the dynamics of protein and protein complexes, and their functions. Although we focus on virus structure here, this field also has widespread application to protein structure and function in general, as well as to the burgeoning technologies of nanoparticles and nanomachines.

ACKNOWLEDGMENTS

We thank Stephen Fuller, Hubert Laude, Yves Gaudin, Winfried Weissenhorn, and Alisdair Steven for ideas and discussions. Density maps were made in some cases from atomic coordinates deposited at the Protein Data Bank (PDB – www.pdb.org) and processed by the BSOFT package (Heymann 2001). The adenovirus 2 and PRD1 cryo-EM capsid densities used in Figure 8 are from the European Bioinformatics Institute (EBI) Macromolecular Structure Database (EMSD – www.ebi.ac.uk/msd). Surface views were rendered with AMIRA (TGS, San Diego USA). Tube and ribbons views were created with MolScript (Kraulis 1991), BobScript (Esnouf 1997), and Render3D (Merritt and Bacon 1997).

This chapter provides an overview of the main techniques used for propagating and identifying viruses. Detailed descriptions can be found in the appropriate journal citations. In some instances, more general references are made to textbooks of laboratory methods, without necessarily citing specific sections.

SYSTEMS FOR PROPAGATING VIRUSES

Viruses can only replicate in living cells. Therefore, an essential first step in propagating viruses in the laboratory is the provision of a suitable culture system. Cell culture is the most widely used method for propagating viruses, but older techniques, such as tissue or organ culture, may still be used for specialized purposes, as may chick embryo and animal inoculation.

Cell culture

GENERAL

Cell cultures are prepared either as single layers (monolayers) on a glass or plastic surface, or as suspensions, the choice depending on their proposed use. Another choice to be made is the type of cell needed for a particular study. Several international repositories can serve as the starting point for reference cell lines and for microbiological reagents. They include the European Collection of Animal Cell Cultures (www.ecacc.org.uk), the American Type Culture Collection (ATCC) (www.atcc.org), Statens Seruminstitut (www.ssi.dk/sw162.asp), and Institut Pasteur (www.pasteur.fr/externe). Detailed information on culture media and specialized techniques is also available from these centers, and in other reference works (Lennette et al. 1988, 1995; Schmidt 1989; Freshney 2000; Murray and Baron 1995).

SAFETY

All procedures involving cell lines should be performed in a class II biological safety cabinet under strict aseptic conditions, both to minimize the risk of contaminating cells with bacteria, yeasts, and mycoplasmas and to protect the worker. Cell lines should be considered potentially hazardous. Although continuous (transformed) cell lines are assumed to be free of infectious agents, they may in fact harbor latent viruses that could infect the worker (Barkley 1979). Safety precautions should include the general measures reviewed by Fleming and Richardson (1995), Lennette et al. (1995), Sewell (1995) and in The laboratory diagnosis of viral infections.

CELL CULTURE MEDIA

Most of the basic culture media used today are chemically defined, but must be supplemented with 1–20 percent serum. This is usually obtained from calf fetuses and must be carefully checked for contamination by viruses, mycoplasma, bacteria, and specific viral antibodies. Serum-free media is also commercially available

for specialized applications (e.g. vaccine development). Cells generally grow well at pH 7.0–7.4. Phenol red is often used as an indicator in the medium, changing progressively from purple at pH 7.8 through red at pH 7.4 to yellow at pH 6.5 (Freshney 2000).

Culture media require careful buffering to stabilize the pH under all conditions. In plastic dishes with unsealed lids, in which exposure to oxygen causes the pH to rise, exogenous CO_2 is required by cell lines, particularly at low cell concentrations, to prevent total loss of dissolved CO_2 and bicarbonate from the medium. In tubes or flasks with tight caps, pH can be adjusted by loosening the caps, changing the medium or placing the vessels in a CO_2 incubator with a gas-permeable cap, as dictated by the indicator. The CO_2 level is critical and can be monitored by a gas analyzer. As little as a 1percent increase can result in cell death.

Medium components should be prepared with endotoxin-free water. Water systems are available to produce type I reagent grade water, which minimizes metal and organic ions leaching from storage containers and prevents bacterial and yeast contamination by being used immediately.

Media, media components, and reagents are sterilized by autoclaving if they are heat-stable (e.g. water, salt solutions, amino acid hydrolysates) or by membrane filtration if they are not (e.g. protein or sugar solutions). The type of membrane is important. Cellulose acetate membranes are best for applications involving low protein binding, and cellulose nitrate membranes for general purpose filtration. Cotton pads, membranes of larger pore size, or commercial prefilters should be used for prefiltering, and membranes of 0.22 μm average pore diameter (APD), for sterilization.

TYPES OF CELL CULTURE

Cell cultures may be either primary or continuous. Primary cultures contain mixtures of cells freshly derived from the tissue of origin, which may be obtained either from laboratory animals or from human material procured in the course of surgery. Some specimens (e.g. foreskin) are not derived from pathological tissues. Tissues from young or embryonic animals give better results than those from adults. The tissues are first minced into 3-mm pieces and the cells disaggregated by one or more treatments with a solution of 0.22 percent trypsin and 0.02 percent versene. The cells are then filtered through sterile gauze, washed by centrifugation in cold growth medium (GM), and finally suspended in GM to the desired concentration. The concentration of viable cells is determined by counting a sample diluted in trypan blue, which selectively stains dead or damaged cells. Tubes or flasks are seeded at approximately 3×10^5 viable cells/ml.

Cell lines are also derived from primary cells, but can be repeatedly subcultured. They fall into two categories. Euploid cells, such as normal human fibroblasts (e.g. MRC-5, WI-38, HFL1), retain their normal karyotype throughout their culture lifespan, rarely give rise to continuous lines and, after approximately 50 generations, stop dividing (Hayflick 1973). They are sometimes called semicontinuous lines. By contrast, aneuploid (or heteroploid) cells, such as those from many human and animal tumors, may give rise to true continuous cell lines (e.g. HEp-2, HeLa, LLC-MK2). Aneuploid cell lines have a chromosome number that is not an exact multiple of the haploid number.

Insect cell lines are continuous cultures derived from, for example, the SF9 ovary (fall armyworm, *Spodoptera frugiperda*) and from mosquitoes (e.g. *Aedes aegypti* and *Ae. albopictus*). The SF9 line, which is grown in special media, is highly susceptible to infection with baculoviruses and can be used for baculovirus expression vectors and other needs. Mosquito lines are used as suspension cultures for the replication of many mosquito-borne viruses. They have special media and subculturing requirements (Lennette et al. 1995).

Suspension cultures can be prepared from many mouse and human leukemias and ascites tumors. They are incubated on shakers or in roller drums or allowed to settle to the bottom of a large culture flask, such as a roller bottle. Alternatively, a spinner apparatus is available that forces normally adherent cells to grow in suspension in a special medium.

Shell vial cultures contain a cell monolayer grown on a coverslip in a 1-dram vial. The vial is then inoculated with the specimen and centrifuged at low speed (700 *g* for 45 min), which apparently distorts the cell surface and renders it more susceptible to viral attachment. After 1–3 days of incubation, irrespective of any cytopathic effects (CPE), the coverslip is washed briefly, and tested by immunofluorescence assay (IFA), nucleic acid hybridization, or other tests for whichever viruses are suspected. Shell vial cultures have been successfully used as a rapid test for adenovirus (Espy et al. 1987), Cytomegalovirus (CMV) (Gleaves et al. 1989; Buller et al. 1992), varicella-zoster virus (VZV) (Schirm et al. 1989), respiratory syncytial virus (RSV) (Smith et al. 1991), and other respiratory viruses (Matthey et al. 1992; Schirm et al. 1992; Olsen et al. 1993).

Microcultures are cost-efficient systems of growing popularity, having overcome earlier problems with cross-contamination between wells, over-oxygenation, and toxic plastics. Microcultures in 24- to 48- and 96-well plates with sealable lids (or tightly fitting lids for CO_2 incubators) are now commonly used in a variety of viral assays.

In 96-well microtiter plates with flat well bottoms, microcultures are ideal for neutralization tests, tissue culture enzyme immunoassay (EIA), monoclonal antibody testing, and many screening assays (Hierholzer and Bingham 1978; Anderson et al. 1985; Lennette et al. 1995; Murray and Baron 1995). Macrocultures in

standard tubes, however, are still used for primary virus isolation because of the ease of setting up stationary or roller cultures in ordinary incubators, of reading the monolayers for CPE and of obtaining sufficient volume of virus culture to use for subpassaging, identification tests, viral genetic analyses, and storage.

Specialized culture systems have been devised to satisfy particular needs. For example, suspension cultures of human peripheral blood lymphocytes are sensitive to the Epstein–Barr herpesvirus, where it is detected by a transformation assay, and, under cocultivation procedures, to the human T-cell leukemia viruses (HTLV) and human immunodeficiency viruses (HIV) (Lennette et al. 1988, 1995; Fields and Knipe 1990; Isenberg 1992). Immortalized human microvascular endothelial cell cultures derived from foreskin are sensitive to a wide variety of viruses under special culture conditions, and have potential use as a model to study the biology of these important cells (Ades et al. 1992). Extracellular matrix systems support the three-dimensional growth of cells as opposed to monolayer cultures. The Matrigel invasion chamber (Collaborative Biomedical Products, Bedford, MA, USA), for instance, can support fastidious cell types and is currently being explored for its use in viral culture and alterations in cell physiology following viral infection (Bissell et al. 1990; Thompson et al. 1991). Finally, large-volume culture systems, such as suspension culture vats, cells on the surfaces of Sephadex beads or other microcarriers, and cells on spirals of Sterilin or other plastic film are used extensively in industry to prepare vaccines, interferons, and monoclonal antibodies (White and Ades 1990).

Mixed cultures of different cell types combined in a single vial have been used successfully to grow a broad range of viruses (Huang and Turchek 2000; Navarro-Marí et al. 1999). A commercial product, Mixed *Fresh-Cells*, available from Diagnostic Hybrids, Inc. (Athens, OH, USA), combines two compatible cell lines optimized for growing particular groups of viruses, e.g. R-Mix for respiratory viruses, E-Mix for enteroviruses and H&V-Mix for herpesviruses. For example, R-Mix consists of a mixed monolayer of mink lung cells (Mv1Lu) and human adenocarcinoma cells (A549) that have been shown in clinical studies to support the detection of influenza A and B viruses, RSV, adenovirus, and parainfluenza viruses 1, 2, and 3 (Barenfanger et al. 2001; St George et al. 2002).

Genetically engineered cell lines offer potential improvements in our ability to grow viruses and to rapidly detect virus infection. Stable transformation of specific virus receptors for HIV-1 (Chesebro and Wehrly 1988) and EBV (Li et al. 1992) into previously nonpermissive cell lines has been shown to permit growth of these viruses. Genetically modified cells that express an easily measured reporter enzyme after infection with a specific virus have also been developed. For example, a transgenic baby hamster kidney cell line (BHKIC-P6LacZ) that contains multiple copies of a virus-inducible HSV promoter sequence linked to the reporter gene *LacZ* developed by Stabell and Olivo (1992) has been used successfully for diagnosis of infections with HSV types 1 and 2 (LaRocco 2000). An FDA-approved diagnostic assay for HSV, based on these cells, is commercially available (ELVIS HSV test; Diagnostic Hybrids, Inc.). For a more comprehensive review of the potential benefits of genetic engineering of cell lines for diagnostic virology, see Olivo (1999).

QUALITY CONTROL

Contamination by bacteria and fungi is an inherent problem of cell culture work. Contamination can be visually detected by appearance of turbidity or color changes due to changes in the pH of the culture medium, or more definitively by microscopic examination of the culture. Detailed protocols for the detection of most bacteria and fungi that would be expected to survive in cell cultures in the presence of the customary antibiotics may be found elsewhere (ATCC 1992). These methods should be incorporated into the quality control program of the media production laboratory to preclude the contamination of cells by detecting organisms in the culture GM.

Contamination by mycoplasmas and viruses is more difficult to detect, because these organisms usually do not cause turbidity or pH changes, may not cause a CPE in the cells, and are able to pass through 0.2 μm filters commonly used for sterile filtration of media and media components. Thus, these agents may be passaged with the cells indefinitely without detection unless specific testing is performed. Primary rhesus monkey kidney (MK), primary African green monkey kidney (AGMK), and primary bovine embryonic kidney cell cultures are particularly notorious for adventitious virus contamination (Hull 1968; Crandell et al. 1978; Schmidt 1989; Eberle and Hilliard 1995). A variety of methods have been described for detection of the mycoplasma species most commonly found in mammalian cell culture, including microbiological culture, DNA staining with fluorescent dyes, mycoplasmal enzymatic assays, IFA, and EIA, hybridization probes, and polymerase chain reaction (PCR) assay. Commercial testing services are widely available for mycoplasmas and viruses and commercial kits, such as the MycoTect test (Invitrogen), MycoSensor PCR Assay (Stratagene), and Mycoplasma Detection Kit (Roche Applied Science) are available that can be incorporated into a quality control program.

Contamination by other cell lines can also occur, the intrusion of HeLa cells into many other lines giving the most problems. Preventative measures that can be taken include working with only one cell line at a time; keeping bottles of medium, trypsin/versene, etc., separate for each cell line; allowing a ‘resting’ period of approximately 30 min between manipulation of different

cell lines in a biological safety cabinet; and decontaminating cabinet surfaces before introducing another cell line to the work area. The species of origin of a cell line can be determined by various immunological, isoenzyme, and cytogenetic tests (ATCC 1992) that are available commercially. Thus, quality control programs for cell culture laboratories must incorporate periodic searches for contaminants of microbiological and cellular origin, because the contaminants may cause irreversible changes in the cell cultures and can completely confound the interpretation of diagnostic tests.

PROPAGATION OF CELLS

Propagating cells by scraping is a physical method of removing adherent cells from the surface of a culture vessel, and is used when enzymatic removal (see below) may be toxic to the cells or may destroy receptors or other important cell surface molecules. The GM is discarded, the cells are physically scraped from the vessel surface with a disposable cell scraper into fresh GM, and the cells are then dispersed by vigorous pipetting to obtain a suspension of single cells. The cells are counted and appropriately diluted for passage to new flasks or other vessels.

Cell counts are used to quantify viable cells for passaging and seeding. They are best performed in the presence of a vital stain, which is excluded by living cell membranes and is incorporated only into dead cells. In the trypan blue vital stain procedure, a sample of the cell suspension is mixed with 0.4 percent dye in physiological saline, placed in the counting chamber of a hemocytometer, and the cells counted at $\times 100$ magnification. The stained (dead) cells and the unstained (living) cells can be counted separately to determine percentage viability if this is desired. Trypan blue and erythrosin B are the dyes most commonly used for dye exclusion tests. Others (e.g. methylene blue, acridine orange, eosin, nigrosin, and safranin) have also been used (Evans et al. 1975). Dyes, such as crystal violet, stain both living and dead cells and are best used to clarify morphology.

Cells can also be propagated by enzyme treatment, a chemical method of detaching adherent cells from the culture vessel with enzymes, such as trypsin, pronase, or collagenase, together with chelating agents, such as versene (tetrasodium ethylenediaminetetraacetic acid (EDTA)). After washing twice with phosphate-buffered saline (PBS), the monolayer is covered with a solution of 0.05 percent trypsin and 0.53 mM versene and placed at room temperature with cell surface down until the cells detach. After vigorously pipetting to break up clumps, the cells are resuspended at the desired concentration in fresh GM.

Cells in suspension cultures are propagated by adding a sample to sufficient GM to give the desired concentration.

For lymphocyte cultures, fresh mononuclear cells can be isolated from whole blood by Ficoll–Hypaque gradient centrifugation and cultured in suspension. Their uses for diagnosis, evaluation of immunity, and detection of disease are numerous, as are the procedures for isolating particular subpopulations of cells from peripheral blood or lymphoid tissues (Markham and Salahuddin 1987; Castro et al. 1988; Coligan and Kruisbeek 1991).

MAINTENANCE OF CULTURES

Once cells have been passaged, routine medium changes are necessary to encourage their viability by feeding them with fresh amino acids, vitamins, glucose, and other metabolic constituents. The initial cell concentration and the metabolic rate of the cells will determine the feeding schedule. Feeding is done with a maintenance medium (MM), which is the regular medium with reduced serum content (1–2 percent serum vs. 10–20 percent used in GM). MM may hold untransformed cell lines at a single cell layer for an extended period, even 2–3 weeks, because it tends not to stimulate mitosis. Diploid cells, with a finite lifespan, can thus be maintained for extended periods without using up the limited number of cell generations available to them.

Cells can also be maintained by subculturing, particularly important for transformed cells, which continue to divide under MM and thus cannot be successfully fed. Transformed (heteroploid) epithelial cells, such as HeLa and HEp-2, metabolize rapidly and should be subcultured twice a week. Alternatively, the seeding concentration of such rapidly proliferating cells may be lowered to reduce subculturing to once a week. Diploid fibroblast cells, such as MRC-5 and WI-38, metabolize slowly and require subculturing only once a week, with a feeding at least once during that week. Suspension cultures must be subcultured, or the volume of medium increased as the cell population reaches approximately 2×10^6 cells/ml, because the viability of suspended cells drops rapidly at higher concentrations.

STORAGE OF CELLS

Cells may be stored by cryopreservation, which provides a ready stock if any is lost through contamination, incubator malfunction, natural senescence, or a genetic drift that may affect their ability to exhibit the expected response in routine assays. Cells are packed by low-speed centrifugation and resuspended in a freeze medium containing serum and dimethylsulfoxide (DMSO) (Schmidt 1989; Mahy and Kangro 1996; Freshney 2000). One-ml volumes are dispensed into cryovials, frozen slowly at approximately 1°C per min, preferably in a controlled-rate freezer, and stored in liquid nitrogen (−165°C).

Cells are recovered from storage by rapidly thawing in a 37°C water bath, diluting the cells with the appropriate

medium, and placing them in a cell culture flask. The medium is replaced after 24 h to remove all traces of DMSO. The medium exchange for a suspension culture requires centrifugation and resuspension in fresh medium.

Tissue and organ cultures

Laboratory cultures of pieces of human embryonic lung, kidney, intestine, and other organs have proven essential to the discovery of many viruses, such as the respiratory coronaviruses and rhinoviruses. Organ cultures are explants of whole tissue (approximately 1 mm^3), so many cell types are present in their natural form, and feeding medium must be perfused through the explants to maintain viability. Once inoculated with a clinical specimen, virus may be detected by cessation of ciliary movement (in lung) or by specific tests for the viral products accumulated in the medium (McIntosh et al. 1967; Tyrrell and Blamire 1967; Caul and Egglestone 1977).

Embryonated eggs

The chick embryo is a versatile host system in diagnostic virology, although its use has been diminished by the development of alternate culture and direct detection methods. It is still vital to the isolation of some influenza viruses, and the size and appearance of pocks on the chorioallantoic membrane (CAM) afford a quick diagnostic criterion for poxviruses. The advantages of eggs include ease of handling, production of large amounts of infectious amniotic or allantoic fluids, and lack of antibody production by the host which might hinder virus identification. Disadvantages include the need to obtain sterile eggs of known age (certified germ-free eggs can be virtually unobtainable in some countries) and the need to eliminate all viable bacteria, yeasts, and mycoplasmas from the patient's specimen before inoculation.

Fertile eggs must be incubated at 37°C in 40–70 percent humidity and rotated about every 4 h to keep the embryo floating in the center of the egg. For influenza virus isolation in amniotic or allantoic cavities, 9- to 11-day-old eggs are needed. For poxvirus isolation in the CAM, 12-day-old eggs are best.

Laboratory animals

Many animal systems have been developed to serve as models of human infection and to produce high-titer antisera for diagnostic tests. Others have been developed for propagating viruses that do not grow in cell cultures. Suckling mice (see Gould and Clegg 1985) are required for the recovery of some coxsackie A enteroviruses, and suckling mice, suckling hamsters, rabbits, mosquitoes, or ticks are needed for some arboviruses. Primates are the most sensitive systems for the hepatitis viruses, with ducks, woodchucks, and mice as alternatives for hepatitis B virus and mice and piglets for hepatitis E virus. In addition, newborn mice or hamsters, young adult guinea-pigs, and primates are required for some of the biosafety level (BSL)-4 agents (e.g. filoviruses, arenaviruses). These highly specialized and dangerous systems are beyond the reach of most laboratories, and the reader should consult other works for details (Lennette et al. 1988, 1995; Isenberg 1992; Murray and Baron 1995).

Animals should be purchased from companies specializing in the breeding of laboratory animals, so that the strain of the species is documented, immunizations for known adventitious organisms are given, and the quality of care (housing, temperature, air filtraton, food, and water) are within the appropriate national guidelines for animal care. The strains of mice and guinea-pigs may be important; often, only a single strain is suitable for a particular virus. Housing of animals in the receiving laboratory is also critical, not only to conform with national regulations on the humane use of animals, but also to minimize the introduction of exogenous microorganisms and cross-contamination.

PREPARATION OF REAGENTS FOR VIRUS IDENTIFICATION

Preparation of viral antigens

Viral antigens may be structural or nonstructural proteins or glycoproteins produced during viral replication, and may be located internally in the virion or be part of the external capsid components. Many are produced in excess during replication and are released into the supernatant fluid as 'soluble' antigens. For some tests, the antigen may simply be the supernatant fluid from the cell culture in which the virus was propagated. For others, intact virus is required at the highest titers achievable, so several freeze–thaw or sonication cycles are applied to the virus culture to disrupt any remaining cells. Again, a particular viral product may need to be enriched in proportion to other products, but not purified in the biochemical sense. For still others, only a specific viral protein can be used in the test, so it must be purified, concentrated, and preserved after removing interfering viral products and medium components. Alternatively, it may be specifically produced by a eukaryotic or prokaryotic gene expression system.

The two most basic concepts are microbiological purity of the starting viral culture and laboratory safety. For purity, starting cultures and final virus products should be proven free of viable bacterial, fungal, and mycoplasmal contamination by appropriate culturing in thioglycolate broth, trypticase soy broth, neopeptone infusion agar streak/pour plates with 5 percent

defibrinated sheep blood, Sabouraud glucose agar slants for yeasts, and Hayflick's biphasic medium for mycoplasma. Depending on the test and the day-to-day usage, many antigens can be preserved by adding thiomersal (thimerosal) or sodium azide to the final product to final concentrations of 0.01 and 0.1 percent, respectively. For safety, the routine laboratory precautions discussed in The laboratory diagnosis of viral infections, must be followed throughout.

For every virus antigen, a parallel 'dummy antigen' should be prepared as a negative control. Dummy antigens are prepared by sham-inoculating cell cultures, eggs, or animals with normal medium and thereafter treating them exactly as for the active preparation.

RELEASING VIRUS FROM CULTURE CELLS

Starting with the highest titers of infectious virus achievable is essential for antigen preparations. Freeze–thaw cycles, sonication and chemical treatments are the most widely used methods for liberating virus from the host cells and for disrupting virions to expose particular antigens (Mahy and Kangro 1996).

For freeze–thawing, cultures with maximal CPE are frozen at −70°C or below, then thawed to a slush, and agitated to dislodge the cells. The procedure is repeated twice and the final material is clarified by low-speed centrifugation.

For sonication, either the cultures may be freeze–thawed but not centrifuged, or the cells may be scraped off the vessel surface with a rubber 'policeman.' The energy level and time are determined in pilot tests; 30–70 watts output for 1–3 min with multiple pulses per minute will generally disrupt the cells without denaturing the antigen. The sonicated material is clarified by low-speed centrifugation.

Chemical treatments may also be used. Alkaline glycine extraction exposes intracellular antigens useful for complement fixation (CF), indirect hemagglutination (IHA), and EIA for many viruses, particularly those that are membrane-associated (Mahy and Kangro 1996). Treating with trypsin or trypsin–versene, followed by sonicating and centrifuging, produces high-titer antigens useful for EIA and hemagglutination (HA) tests for many viruses. Antigens for use in immunofluorescence tests may be prepared from infected cells disaggregated with trypsin and washed.

VIRUS INACTIVATION PROCEDURES

Viruses can be inactivated to permit safe handling. Choice of inactivation strategy is dictated by the lability of the particular virus and the stability of the viral antigens. Three principal methods used for virus inactivation include sonication, β-propiolactone (BPL) treatment, and radiation (Mahy and Kangro 1996).

Sonication can disrupt virus particles and cleave macromolecules if sufficient energy is applied. The optimum power, number of cycles and length of time must be determined for each virus and test.

BPL treatment is widely used to inactivate viruses because it generally does not interfere with antigen test systems. Cultures are clarified by centrifugation and mixed with BPL in the presence of tris(hydroxymethyl)amino-methane (TRIS) buffer, the final BPL concentration and incubation time having been previously determined in pilot tests. They are then clarified again, adjusted to pH 7.3–7.4 as needed and preserved with thiomersal or sodium azide.

Radiation is a very effective means for inactivating viruses, but must be carried out by people trained and certified for such procedures. The clarified virus/antigen is exposed in an unbreakable container in an ice bath to a ^{60}Co γ source. The dosage required for complete inactivation of the virus (Table 1) is estimated from dose–response curves. The product is tested for residual infectivity and for potency (Gamble et al. 1980).

Other virus inactivation methods are useful for specific purposes, but should not be relied upon to insure complete inactivation for some viruses. For immunoperoxidase assays (IPA) and IFA, infected cells may be fixed with acetone for 10 min at 4°C, which stabilizes viral proteins by partial denaturation and preserves morphological structure and immunological reactivity. Alternatively, viruses can be inactivated with 10 percent formalin at pH 7.0; methanol or ethanol (4 min at 4°C); acetone/methanol 50:50 (Lennette et al. 1995); 80 percent acetone (Anderson et al. 1985); or photochemically with psoralen and related compounds (Hanson et al. 1978). Copper-catalyzed sodium ascorbate preserves CF and IHA antigens of herpes simplex virus (HSV) (White et al. 1986); certain detergents (e.g. 1 percent Nonidet P-40, 0.1–0.5 percent sodium lauryl sulfate, Tween-20, or Tween-80) can break up virus envelopes without destroying antigenic activity.

ANTIGEN EXTRACTION PROCEDURES

Extraction procedures can free antigens of nonspecific inhibitors, anticomplementary reactions, competing proteins and lipoproteins, and undesired reactions related to the viral host system. For example, HA anti-

Table 1 *Dosage of ^{60}Co γ-irradiation required for complete inactivation of viruses*

Mrad[a]	Viruses inactivated
0.5	Cytomegalovirus
1.5	Influenzavirus

3.4	Lymphocytic choriomeningitis virus

a) Megarad, or 10^6 rad (rad, radiation absorbed dose).

gens must be free of serum antibodies, host-cell components and microbial contaminants that may agglutinate the erythrocytes used in the assay. Some antigens are enhanced in reactivity by treatment with freeze–thaw cycles, sonication, Tween-80, fluorocarbon, ether, or other organic solvents (Norrby 1962; Chappell et al. 1984). The Tween-80–ether extraction method is found in Mahy and Kangro (1996). The sucrose–acetone–BPL and fluorocarbon methods are briefly described here, by way of example. Alternatively, nonionic detergents, such as Nonidet P-40, high concentrations of salts in the presence of EDTA and β-mercaptoethanol, and other extracting agents can be used to prepare viral antigens (Isenberg 1992; Mahy and Kangro 1996).

The sucrose–acetone–BPL extraction method is useful for the CF and HA antigens of some viruses, including togaviruses (Venezuelan equine encephalomyelitis virus) and flaviviruses (Dengue virus, Japanese B encephalitis virus, Rocio virus, St. Louis encephalitis virus, Yellow fever virus and other formerly group B arboviruses) (Schmidt and Lennette 1971; Chappell et al. 1984). A 40 percent suspension of infected tissue (e.g. mouse brain) is homogenized in borate-saline, pH 9.0 in ice; 1 M TRIS/borate-saline equal to 1/10 the volume of suspension is added, followed by cold BPL drop-wise to a final concentration of 0.1–0.3 percent. After mixing for 1 day in the cold, an equal volume of 17 percent sucrose in distilled water is added, together with 20 volumes of cold acetone chilled to −20°C per volume of homogenate, still in ice and with mixing. After vigorous shaking the tissue is allowed to settle out at –20°C for 30 min, and the supernatant acetone is aspirated. The preparation is again extracted with acetone, keeping the 20:1 ratio. The antigen may be preserved best as a freeze-dried powder, but should be reconstituted in borate-saline and centrifuged at 10 000 *g* for 1 h before use.

For fluorocarbon extraction, the centrifuged starting material is placed in a stainless steel vessel in an ice bath for high-speed homogenization. Sufficient fluorocarbon (e.g. Genetron; CF_3CCl_3) is added to obtain a 2:1 ratio of antigen to fluorocarbon and the mixture is homogenized at full speed for 4–6 min. The aerosol is allowed to settle in the closed container for 1 h in ice. The suspension is then decanted into bottles or tubes for layer separation at 1000 *g* for 20 min at 4°C; the supernatant is the treated antigen (Gessler et al. 1956).

Viral antigens can be partially purified by adsorption/elution from erythrocytes or from calcium phosphate gels (Mahy and Kangro 1996). More effective purification is achieved by various types of solid-phase immunological adsorption/elution techniques and by affinity chromatography. Antigens may be immunoaffinity-purified by passing viral cultures (usually after SLS or enzyme treatment to disrupt virions and liberate proteins) through columns containing gel beds coated with specific antibody, or beds of monoclonal antibody-bound protein A–sepharose beads, etc. Other types of affinity chromatography use enzyme- or substrate-bound matrices. The reader is referred to other sources for detailed methods of affinity chromatography (Eisenberg et al. 1982; Wilchek et al. 1984; Chong and Gillam 1985; Harlow and Lane 1988).

SYNTHETIC AND EXPRESSED ANTIGENS

Polypeptides representing discrete viral antigens can be chemically synthesized for use in diagnostic assay and special studies. However, synthetic peptides are typically restricted to single linear epitopes that do not possess the secondary and tertiary structure of more complex antigens. Alternatively, various commercially available recombinant gene expression systems can be used to construct complex viral antigens that may be more suitable for viral diagnostic assays. Prokaryotic expression systems are convenient and inexpensive, but possess different processing pathways which prevent the amino terminal modifications, disulfide bond formation, and glycosylation required for many viral antigens to be active. Eukaryotic expression systems are more complex and expensive, but are closer to the natural mode of replication of the virus. Thus, post-translational modifications necessary for antigenicity are more likely to take place. Many viruses can serve as expression vectors in eukaryotic systems. For example, baculovirus is particularly useful because it can be 'engineered' to incorporate various tag genes which make it possible to purify and identify the virus or its expressed products. Once the gene for the desired antigen has been inserted into the recombinant baculovirus, the virus is grown at 27°C in SF9 or SF21 fall armyworm ovary cells and the desired antigen identified by IFA, EIA, or western blot. The reader is referred to other sources for the details and methods of gene expression systems (Smith and Johnson 1988; Bennink and Yewdell 1990; Vialard et al. 1990; Ausubel and Brent 1991; Jarvis 1991; Taylor et al. 1992; Cox et al. 1993; Alberts et al. 1994).

Preparation of high-titer antisera

High-titer antisera to viruses and viral antigens are readily produced in animals for use in diagnostic assays. Animal-derived antisera were the backbone of early virology, being widely used to distinguish between strains and serotypes and to study the antigenic make up of viruses. Polyclonal antisera of high titer ('hyperimmune sera') is prepared by repeated injection of virus or viral antigen into, for example, rabbits, mice, and guinea-pigs, or larger animals, such as goats and horses. The general procedure is to clarify the preparation by centrifugation, mix it with an equal volume of Freund's incomplete adjuvant or a synthetic muramyl dipeptide adjuvant, inject the mixture into suitable sites between two and four times biweekly, and obtain a blood sample

10–14 days after the final injection. The pre- and post-immunization sera are then tested for the desired antibody. Use of other adjuvants, injection in multiple sites with or without adjuvant, techniques to minimize the development of host-cell antibodies, and preparation of antigen/antibody complexes on solid matrices, such as staphylococcal protein A, are described in other sources (Hierholzer et al. 1991; Lennette et al. 1995; Murray and Baron 1995; Mahy and Kangro 1996).

Preparation of monoclonal antibodies

Monoclonal antibodies have become a vital immunological reagent since their inception in 1975 (Scharff et al. 1981; Peter and Baumgarten 1992; Lennette et al. 1995; Murray and Baron 1995). Many variations in their production have been described, including immunization in vitro and EBV-transformation techniques (Seigneurin et al. 1983; Boss 1986; Foung et al. 1986; Treanor et al. 1988). Suitable methods are described by Goding (1996).

ISOLATION AND IDENTIFICATION OF VIRUSES FROM CLINICAL SPECIMENS

Specimen collection and treatment

To avoid misleading results, it is of the utmost importance that adequate specimens are taken from sites appropriate to the clinical findings and then correctly stored and processed. The type of specimen and the manner of collection depend upon the laboratory methods to be used and on the sites clinically affected (Johnson 1990; Hierholzer 1991, 1993; Lennette et al. 1995). Specimens should ideally be collected within a few days of the onset of symptoms, because most viruses are shed only in the initial stages of illness. Swab specimens are placed in 2 ml of transport medium (e.g. tryptose phosphate broth with 0.5 percent gelatin, veal heart infusion broth or trypticase soy broth), preferably without antibiotics to allow the culture of bacteria and mycoplasmas. Nasopharyngeal aspirates are excellent specimens for respiratory viruses and are collected with a neonatal mucus extractor and mucus trap to which transport medium is added (Waris et al. 1990). According to the circumstances, other specimens may include urine, stool, whole blood, serum, cerebrospinal fluid, biopsy and autopsy specimens, and swabs or scrapings of vesicular lesions. Specimens are placed on wet ice and transported to the laboratory for immediate culturing. If testing is not possible within 5 days of collection, they are frozen on dry ice and stored at –70°C until they can be processed, although this may reduce the amount of viable virus. Before inoculation into the appropriate host system, specimens are treated with antibiotics, mixed vigorously, and clarified by centrifuging at 1000 *g* for 3 min at 4°C to remove cell debris and bacteria. Many viruses require one or more subpassages for recovery.

Procedures for isolating viruses

CELL CULTURES

Cell cultures should include a continuous human epithelial line (e.g. HEp-2 (Johnston and Siegel 1990); KB, A549 (Woods and Young 1988), HeLa); a human embryonic lung diploid fibroblast cell strain (e.g. HLF, HELF, MRC-5, WI-38); human lung mucoepidermoid cells (NCI-H292) to replace MK cells for most applications (Castells et al. 1990; Hierholzer et al. 1993b); and human rhabdomyosarcoma cells (RD) for the broadest coverage of viruses within practical limitations (Matthey et al. 1992). Treated specimens are adsorbed on to cell monolayers whose GM has been decanted. MM is added and cultures are incubated at 35–36°C up to several weeks, with subpassaging as required. Toxic specimens (urine, stool, tissue homogenates) should be decanted before MM is added.

Some cell types and certain viruses require roller cultures, whereas others do best as stationary cultures during their incubation period. In general, all tube cultures of MK, AGMK, and their derivative cell lines (Vero, BSC-1, LLC-MK2, etc.), all diploid fibroblast cell cultures, and NCI-H292 cells should be rolled in roller drums or agitated on rocker platforms to remove toxic byproducts from the cell surface and to replenish critical nutrients to the cells more quickly. Cultures of human embryonic kidney (HEK), HEp-2, KB, A549, and HeLa do not need to be rolled, except for the isolation of RSV and measles virus.

Small variations in media composition and incubation temperature are also important for the isolation of certain viruses. For instance, viruses may require prior treatment with trypsin (Almeida et al. 1978; Sanchez-Fauquier et al. 1994), or the cells may require trypsin in the MM to render them sensitive to certain viruses (Itoh et al. 1970; Frank et al. 1979; Agbalika et al. 1984; Castells et al. 1990). Cooler incubation temperatures (33–35°C) are best for less invasive viruses, such as coronaviruses, rhinoviruses, and the enteroviruses that cause hemorrhagic conjunctivitis. Finally, whenever MK or AGMK cells are used (e.g. for influenza, measles, or rubella), one should presume that simian adventitious agents are present and may confound the isolation and identification of human viruses (Hull 1968; Eberle and Hilliard 1995).

Viral growth is usually detected as CPE in the infected cell monolayer by scanning at ×40–100 magnification and observing in greater detail at ×200–400 magnification (Figure 1). The type of CPE and the time required for it to appear in a particular cell type are suggestive of the type of virus present. Thus, careful

observation of the monolayers is important for applying the proper identification tests.

EMBRYONATED EGGS

Except for influenza and poxviruses, chick embryos have been largely superseded by cell cultures for virus isolation and identification.

The amniotic route of inoculation is used mainly for primary isolation of influenza viruses, and the allantoic route for serial passages and for obtaining large quantities of virus. Embryos (approximated 10 days old) are inoculated by well-established methods and the fluids are harvested 2–4 days later.

The chorioallantoic membrane (CAM) method is used mainly for poxviruses. The membranes of 12-day-old embryos are inoculated through an opening in the shell about halfway along the long axis of the egg, the CAM having first been pulled away from the shell by applying negative pressure to a second hole drilled over the natural air sac. The CAM is inspected for the appearance of pocks after further incubation for 2–4 days.

For a detailed account of chick embryo methods, see Barrett and Inglis (1985) and Lennette et al. (1995).

LABORATORY ANIMALS

Like chick embryos, animals have largely been superseded by other systems, although they are occasionally

used for special purposes, such as the isolation and partial characterization of coxsackieviruses in suckling mice, which can be inoculated both intracerebrally and intraperitoneally (Gould and Clegg 1985).

For use of other animal systems, the reader is referred to chapters dealing with the relevant virus groups in this volume and elsewhere (Lennette et al. 1988, 1995; Murray and Baron 1995).

Recovery and identification of viruses

Table 2 summarizes the relative value of a range of methods for isolating and propagating human viruses. Further details may be found in Isenberg (1992), Lennette et al. (1995), and Murray and Baron (1995).

ADENOVIRUSES

Adenoviruses (see Adenoviruses) are associated with diverse clinical syndromes. They are spread by droplets, fomites, and the fecal–oral route; some serotypes are also spread venereally. Most serotypes replicate readily in HEK, A549, HEp-2, KB, and NCI-H292 cells, with or without rolling, producing grapelike clusters of round, refractile, enlarged cells. Adenoviruses grow in most of the same cells as herpes simplex viruses, but more slowly (3–14 days), depending on serotype, and make more discrete, irregularly shaped cell clusters. Adenoviruses can be adapted to replicate in fibroblast cells, but the CPE develops slowly and infectivity titers are low. Types 40 and 41, associated with infant gastroenteritis, grow best in an Ad5-transformed HEK cell line (Graham-293 cells) or in HEp-2 under a fortified Opti-MEM medium containing 0.4 percent fetal calf serum and 0.1 percent 2-mercaptoethanol. The adenoviruses are among the easier viruses to identify because they are unique in producing in cell culture very large quantities of soluble antigens with many type- and group-specific properties that lend themselves to a wide variety of diagnostic tests. Adenoviruses are distinguished from other viruses by electron microscopy (EM), latex agglutination (LA), IFA, IPA, EIA, time-resolved fluoroimmunoassay (TR-FIA) (Hierholzer et al. 1987; Brown et al. 1990), DNA probes, restriction enzyme analysis (REA) (Adrian et al. 1986), PCR assay (Hierholzer et al. 1993c), and cytological and inclusion-body staining methods. Adenoviruses are serotyped by HI and serum neutralization (SN) tests (Hierholzer 1992).

'ARBOVIRUSES'

The togaviruses (see Togaviruses), flaviviruses (see Flaviviruses), arenaviruses (Arenaviruses), rhabdoviruses, filoviruses (Filoviruses), and bunyaviruses (Bunyaviridae) contain most of the agents covered by the term 'arboviruses' and many rare and unusual viruses that cause disease in geographically distinct parts of the world. Arboviruses often have special isolation requirements. Certain arboviruses can be isolated in primary hamster kidney cells, primary chick or duck embryo cells, or derivative cell lines such as AP61 mosquito cells, BHK-21 hamster kidney cells, Vero (African green monkey kidney cells), and LLC-MK2 rhesus monkey kidney cells, after 2–10 days of culture. For example, the Sin Nombre hantavirus is a bunyavirus that can be propagated in the Vero E6 cell line after growth in deer mouse lungs (Elliott et al. 1994). The CPE may not be apparent at first, but becomes generalized in subpassages or forms plaques under agarose. Other arboviruses grow best in mosquito suspension-cell cultures at 20–30°C, in which replication is detected by subpassaging to monolayer cultures, in which CPE may be evident, or by HA/HI, EIA, IFA, CF, SN, or nucleic acid tests for the specific viruses suspected. Still other arboviruses can be recovered only in whole animal systems such as chick embryos, suckling mice or hamsters, or mosquitoes. Fortunately, most diagnostic laboratories will not encounter these viruses, either because of their rarity in most parts of the world or because of their requirement for BSL-3 or -4 containment facilities. The reader is therefore referred to other works that detail the isolation requirements and systems, the specific identification tests and the laboratory precautions for these viruses (Fields and Knipe 1990; Lennette et al. 1988, 1995; Murray and Baron 1995).

CORONAVIRUSES

The human coronaviruses (see Coronaviruses, toroviruses, and arteriviruses) cause a significant proportion of 'common colds' and are spread by droplet route. Because these viruses are extremely labile and difficult to recover by culture, they are best identified directly in nasal and throat specimens by IFA, EIA, TR-FIA, or reverse transcription (RT)-PCR. The viruses growing in diploid fibroblast cells (229E virus) or in RD cells (OC43 virus) do not cause discernible CPE during their replication phase. Only when viral replication is complete and the virus titer has peaked (at approximately 10^7 tissue culture infective doses ($TCID_{50}$/0.1 ml), after 26–30 h of roller incubation, do changes begin to be evident in the monolayer. For the next several days, CPE develops as a uniform degeneration across the monolayer. The CPE becomes complete concomitant with autolysis of the newly formed virions. By this time, little infectious virus is left in the culture (Hierholzer 1976; Schmidt et al. 1979). The peplomers constitute the primary antigen detected in all tests, including the HI test for strain OC43 (Schmidt et al. 1979; Hierholzer et al. 1994a). Alternatively, the viral RNA can be identified by RT-PCR (Vabret et al. 2001).

+, Suitable for growth of virus; ±, partially suitable, i.e. some strains do not grow, or titers are low; −, unsuitable; Amn., amniotic cavity; All., allantoic cavity; CAM, chorioallantoic membrane; CE, California encephalitis; EEE, Eastern equine encephalitis; Embry., embryonated; JE, Japanese encephalitis; HIV, human immunodeficiency virus; HTLV, human T-cell leukemia/lymphoma virus; LCM, lymphocytic choriomeningitis; SARS, severe acute respiratory syndrome; SLE, St. Louis encephalitis; VSV, vesiculovirus; WEE, Western equine encephalitis.

is distinct from the other human coronaviruses in that it readily grows in MK, Vero, or Vero E6 cells, but does not grow or grows poorly in most other cell lines (Ksiazek et al. 2003). CPE is focal, with cells giving a rounded, refractile appearance, and is rapidly progressive, leading to detachment of the cell monolayer. Because culture requires BSL-3 procedures and facilities, diagnosis of SARS coronavirus infection is best made by serology (EIA, IFA) or detection of viral RNA by RT-PCR assay.

GASTROENTERITIS VIRUSES

These viruses (see Human enteric RNA viruses: Astroviruses; and Reoviruses, Orbiviruses, and Coltiviruses) also belong to diverse families and have unique requirements for culture. Rotaviruses will replicate in BSC-1, MA104, and AGMK cells under roller conditions with trypsin treatment. Astroviruses replicate in human CaCo-2 and PLC/PRF/5 cells under a fortified medium with trypsin (Taylor et al. 1997; Brinker et al. 2000). The noroviruses and sapoviruses cannot be isolated in the laboratory (Koopmans and Horzinek 1994; Lennette et al. 1995). The gastroenteritis viruses can be distinguished by EM, EIA, and RT-PCR (Erdman et al. 1989; Coulson et al. 1999; Rabenau et al. 2003).

HEPATITIS VIRUSES

Hepatitis A virus, a picornavirus (see Hepatitis A and E), replicates in MK cultures in 1–4 weeks, but is noncytolytic. It is detected by EIA or RT-PCR. The hepatitis B virus, hepatitis C virus, hepatitis D virus, and hepatitis E virus do not grow in routine cell cultures and must be diagnosed by antigen (EIA or TR-FIA), or nucleic acid detection assays (Siitari et al. 1983; Balayan 1993; Wilber 1993; Kurstak et al. 1995).

HERPESVIRUSES

The herpesviruses are spread by aerosolized droplets, fomites, and direct contact, and cause a wide range of ocular, oropharyngeal, genital, and generalized disease in humans. They have three types of CPE in cell culture. HSV-1 and -2 grow well in many cell types, producing grapelike clusters of round, refractile, enlarged cells often identical to adenovirus CPE in HEK, HEp-2, KB, HeLa, A549, HLF, NCI-H292, primary rabbit kidney, and other cells. At complete CPE, all cells become lysed and detached from the vessel surface. HSV-1 grows fast (1–2 days), makes fewer clusters, and may produce ballooned, multinucleate giant cells with granulated cytoplasm. HSV-2, usually a genital isolate, grows more slowly than type 1. HSV does not require roller cultures, but HEp-2, NCI-H292, and fibroblast cells will probably be on roller or rocker apparatus for the benefit of other viruses to which these cells are susceptible.

CMV is notably labile. The only herpesvirus that is shed in great amounts in the urine, it replicates slowly (12–30 days) in roller cultures of diploid fibroblast cells. CMV produces giant-cell CPE resembling elongated foci of refractile, swollen cells, somewhat akin to measles CPE.

Varicella-zoster virus (VZV), the cause of chickenpox and herpes zoster (shingles), also grows slowly in fibroblasts on roller culture. It produces a CPE characterized by enlarged, round, glassy cells in small foci in 2–10 days, which is thus distinct from that caused by CMV. VZV can produce large foci of multinucleate giant cells when the individual foci coalesce.

Epstein–Barr virus (EBV) is associated with infectious mononucleosis, Burkitt's lymphoma, and nasopharyngeal carcinoma; human herpesvirus 6 (HHV-6), the cause of roseola infantum (exanthema subitum or 'fourth disease') in children; human herpesvirus 7 (HHV-7), the probable cause of some roseola cases; and human herpesvirus 8 (HHV-8), the cause of AIDS-associated Kaposi's sarcoma (Chang et al. 1994). EBV requires special conditions and cells for successful cultivation in the laboratory. In culture, it infects both B lymphocytes and epithelial cells with the CD21 receptor; HHV-6 grows best in primary $CD4^+$ T lymphocytes rendered more susceptible by the presence of antibody to CD3 (Pellett et al. 1992; Yasukawa et al. 1993; Hall et al. 1994); HHV-7 also replicates in $CD4^+$ T-lymphocytes (Black and Pellett 1993; Lusso et al. 1994; Tanaka et al. 1994). HHV-8 has been difficult to isolate from cell culture, although limited infections of CD19 B lymphocytes, macrophages, and certain endothelial cells has been demonstrated (Blackbourn et al. 2000).

Herpesviruses are readily visualized by EM, the icosahedral nucleocapsid and the baggy envelope being prominent. The viruses are commonly speciated by IFA, EIA, LA, and SN tests and by DNA hybridization and PCR assays (Buller et al. 1992; Drew 1992; Perez et al. 1995).

ORTHOMYXOVIRUSES

Influenza A, B, and C viruses (see Orthomyxoviruses: influenza) are spread by aerosol droplets and fomites, and are best recovered in roller cultures of primary MK and MDCK cells and in intact chick embryos. Chick embryo cells, MDCK, and other cells require rolling and a fortified medium containing trypsin 2 μg/ml for optimal sensitivity. The CPE may be seen as a combination of syncytia, rounding, and degeneration. The syncytia caused by influenza B virus may be accompanied by vacuolation. Influenza CPE may develop in 4–7 days, but cultures should be blind-passaged and held an additional week. Because the cells rarely become detached and may not have an obvious CPE, virus detection in MK cultures is verified by hemadsorption with chicken or guinea-pig erythrocytes, and in MDCK

cells by HA. Some strains of influenza A and B can be isolated only in 9- to 11-day-old chick embryos. The viruses are then typed by HI, IFA, EIA, TR-FIA or RT-PCR assay (Frank et al. 1979; Grandien et al. 1985; Walls et al. 1986; Bucher et al. 1991; Ziegler et al. 1995; Stockton et al. 1998).

Hemadsorption is a fast and convenient method for detecting orthomyxoviruses (influenza A, B, C) and non-RSV paramyxoviruses (parainfluenza 1, 2, 3, 4A, 4B; mumps; measles) in cell cultures. It is even used in the presence of CPE to obtain a quick distinction from other virus groups that may cause similar CPE in the same types of cultures. The supernatant fluid from the cell culture is decanted into a sterile tube at the end of the incubation period (7–10 days), to conserve virus and viral antigens for passaging and testing. The monolayer is washed twice with 2–3 ml of plain Hank's balanced salt solution (HBSS) at room temperature; 1 ml of fresh HBSS is added, followed by 0.2 ml of 0.4 percent mammalian erythrocyte suspension from the appropriate species. The tube is incubated stationary with the fluid covering the monolayer. The test is read three times at 20-min intervals by agitating the tube in a sideways motion and then observing at ×40–100 magnification for erythrocytes firmly attached to the cultured cells (positive) or floating free in the fluid (negative).

PAPOVAVIRUSES

The papovaviruses (see Papillomavirus; and 24, Polyomaviruses) consist of two genera (*Papillomavirus* and *Polyomavirus*), but only *Polyomavirus* can be isolated in cell culture. The BK polyomavirus can be recovered in NCI-H292 and diploid fibroblast cells, and the JC polyomavirus replicates in primary human fetal glial cells, but both viruses may be missed because their CPE develops slowly and may be ill-defined. It is a granular, degenerative, slowly lytic CPE, similar to that caused by reoviruses. BK virus is identified by hemagglutination inhibition (HI) tests at 4°C with human 'O' erythrocytes and specific antiserum; BK and JC viruses are identified by EIA, SN, hybridization probes or PCR assay. The other genus, papillomaviruses, cannot be propagated in cell culture so are identified in biopsied tissues by antipeptide EIAs and by hybridization probes and PCR (Eklund and Dillner 1995; Ylitalo et al. 1995).

PARAMYXOVIRUSES

The human paramyxoviruses (General properties of the paramyxoviruses) are parainfluenza types 1, 2, 3, 4A, 4B, mumps, measles (rubeola), RSV and the recently identified human metapneumovirus (hMPV) (van den Hoogen et al. 2001). The parainfluenza and mumps viruses replicate well in roller cultures of NCI-H292 cells under a fortified medium containing trypsin 1.5 μg/ml for optimal sensitivity, and in primary MK cells without trypsin (Meguro et al. 1979; Castells et al. 1990). The CPE induced by these viruses may develop in 4–7 days, and is a combination of syncytia and rounding. The syncytia may be accompanied by a granular degeneration with parainfluenzavirus types 1–4. Mumps virus often gives rise to large syncytia. The cultures must generally be blind-passaged and held an additional week to ensure viral growth. The cells rarely become detached, and may not show obvious CPE at all, so NCI-H292 or MK cultures for these viruses must be hemadsorbed with guinea-pig, human, or monkey erythrocytes at the end of the culture period and then typed by HI, IFA, EIA, TR-FIA or RT-PCR assay (Grandien et al., 1985; Van Tiel et al. 1988; Hierholzer et al. 1989, 1993a; Takimoto et al. 1991; Echevarria et al. 1998).

Measles virus can be grown in a wide range of cell culture systems, but is most successfully isolated in the Epstein–Barr virus-transformed marmoset B lymphoblastoid cell line, B95a (Kobune et al. 1990). CPE is characterized by presence of classical multinucleate giant cells resulting from fusion of adjacent cells. Because the CPE may develop slowly and not be recognized, the monolayers should be screened to ensure detection of the virus. Measles can be identified by HI tests with vervet monkey erythrocytes, IFA, EIA, SN, or RT-PCR assay (Hummel et al. 1992; Nakayama et al. 1995).

RSV produces a distinct syncytial CPE in HEp-2, HeLa, and NCI-H292 cells in 5–12 days in roller cultures. The balled-up syncytia usually become detached from the glass surface and float freely in the medium. Some strains of RSV, particularly of group B, produce more cellular degeneration than syncytia in HEp-2 and NCI-H292 cells. Group A and B strains of RSV are readily identified by IFA, EIA, TR-FIA, or RT-PCR (Freymuth et al. 1991; Waris 1991; Cane et al. 1992; Hierholzer et al. 1994b). Details on paramyxovirus typing are found elsewhere (Popow-Kraupp et al. 1986; Ahluwalia et al. 1987; Akerlind et al. 1988; Anderson et al. 1991).

hMPV produces a delayed cellular degeneration with round and refractile cells and occasional syncytial formation in tertiary MK and LLC-MK2 cells supplemented with 1.5 μg/ml trypsin. The appearance of CPE can take up to 2 to 3 weeks from inoculation of the specimen, or may not be recognized, and therefore cultures should be screened to ensure detection of the virus. HMPV is identified by RT-PCR assay (Boivin et al. 2002; Falsey et al. 2003).

PARVOVIRUSES

The human parvovirus B19 (see Parvoviruses) causes 'fifth disease' (erythema infectiosum) and is easily spread by aerosolized droplets and fomites in schools, and vertically to the fetus during the first trimester of pregnancy (see Virus infections in

immunocompromised patients). The virus can be grown in specialized erythropoietic stem cell cultures, but not in standard culture systems. Therefore, B19 infection is established by EIA testing of the patient's acute-phase serum for antiviral IgM antibodies or by PCR assay for viral DNA (Heegaard and Brown 2002).

PICORNAVIRUSES

This large family (see Picornaviruses) includes the enteroviruses (poliovirus 1–3, 23 coxsackie A viruses, six coxsackie B viruses, 31 echoviruses, and five more recent enteroviruses), and the rhinoviruses (approximately 125 serotypes). The enteroviruses are spread by aerosolized droplets, fomites, and the fecal–oral route, whereas the rhinoviruses are spread by aerosols and fomites only (Agbalika et al. 1984; Dick et al. 1987; Mandell et al. 1990). These viruses produce a 'shrunken cell degeneration' CPE in NCI-H292, MK, RD, trypsin-treated MA-104 and diploid fibroblast cells, preferably in roller cultures, although some coxsackie A viruses grow only in the brain of suckling mice. The CPE is often observed as tadpole-shaped, shrunken cells with pyknotic nuclei, beginning in patches at the edges of the monolayer and progressing inward. CPE for polioviruses and some coxsackie B viruses is quite rapid, becoming complete in 1–3 days with all cells detached from the glass. CPE for the remaining enteroviruses and the rhinoviruses generally requires 4–7 days or longer, is often characterized by individual small, rounded, and sometimes refractile cells or by a degenerative appearance across the monolayer, and may never become complete. Subpassaging is helpful. The variable CPE found in enterovirus- or rhinovirus-infected cells is not diagnostically confusing, however, because these viruses do not hemadsorb, rarely hemagglutinate with any species of erythrocytes, and do not interfere with test systems for other viruses. Enteroviruses are distinguished from rhinoviruses by acid- and chloroform-lability tests in which both genera are chloroform-stable, but only enteroviruses are acid-stable, or by group-specific IFA or RT-PCR assay (Hyypia and Stanway 1993; Egger et al. 1995; Halonen et al. 1995; Lipson et al. 2001). The viruses can be serotyped by type-specific SN tests.

POXVIRUSES

Vaccinia and certain other poxviruses (see Poxviruses) can be isolated in MK, Vero, NCI-H292, and diploid fibroblast cells. Their CPE is characterized as cell fusion with plaques. Plaques ranging from 1 to 6 mm in diameter (depending on the virus) are formed in 2–4 days, during which the infected cells fuse, form cytoplasmic bridging, and then disintegrate. Some poxviruses produce plaques on the CAM of 12-day chick embryos. Identification is accomplished from the type and size of plaques formed and by EM, HI, EIA, IFA, REA, and PCR.

REOVIRUSES

Reoviruses 1–3 can be isolated from throat and rectal specimens in NCI-H292, MK, and HeLa cells under stationary or roller conditions after 5–14 days of culture, but, unlike other members of the family *Reoviridae* (see Reoviruses, Orbiviruses and Coltiviruses), have never been clearly associated with human disease. In cell culture they cause a slow lytic degeneration with granulation of the cytoplasm, similar to polyomavirus CPE. MK cultures should be rolled. Reoviruses are easily visualized by EM and serotyped by SN and HI tests with human type 'O' erythrocytes.

RETROVIRUSES

The HIV and HTLV viruses (see Prions of humans and animals) also require specialized systems for isolation and identification, and will not be recovered by standard culture methods. They are identified by EIA, western blot, or RT-PCR assay (Isenberg 1992; Persing and Smith 1993; Signoret et al. 1993).

RUBELLA

Rubella virus, a togavirus (see Rubella), was originally detected because of its ability to prevent another virus from infecting the cells in which it was replicating. Current diagnostic testing for rubella may employ specialized cultures in which CPE may become evident. Rubella can, under certain conditions, cause an ill-defined and variable CPE in rabbit cornea, rabbit kidney, and Vero cells. Usually, however, rubella is detected by the interference test, in which replication of another virus (e.g. echovirus 11 or coxsackie virus A9) is inhibited by prior inoculation of the test material. A positive result may be confirmed by HI, EIA, LA, TR-FIA, or RT-PCR assay (Shankaran et al. 1990).

The interpretation of any culture isolation result or of any test used to identify the isolate depends on the methods employed, but viral growth alone should never be considered pathognomonic. The association of an isolate with disease depends on the clinical data obtained with the specimen and on the known epidemiology of the virus. Thus, careful virus isolation and identification test results, coupled with sound epidemiological data are the key to accurate diagnosis of viral infections.

Virus gene expression	5		

INTRODUCTION

An essential feature of all viruses is that they are obligate intracellular parasites and are biochemically inert in the extracellular environment. They have no mechanisms for energy generation, protein translation, or a host of other complex biochemical processes that are essential for the maintenance and growth of living cells. Consequently they are totally dependent on the structure and function of cellular machinery to enable the macromolecular synthesis required during the reproductive phase of their life cycles.

Because they co-opt cellular structures and functions to facilitate their own replication, viruses survive successfully with small genome sizes. The number of genes encoded within different viruses ranges from one in the smallest to a few hundred in the largest and most complex. With the largest viruses many of their genes are not required for replication per se, but are involved in the avoidance of host immune defense mechanisms.

From the perspective of their genetic organization, viruses are the most varied organisms in the biosphere. In addition to the wide range in genome size exhibited by different viruses, every conceivable means of nucleic acid genetic storage mechanism seems to have been adopted within the virological spectrum. Viral genomes can be encoded by DNA or RNA, which can be single-stranded or double-stranded, of positive or negative polarity, and comprise single or multiple components. In addition, retroviruses and hepadnaviruses alternate between DNA and RNA as the carrier of their genetic information at different stages in their life cycles.

Despite the wide variation evidenced between viruses, there are a number of features that are common to the replication of all. To be rescued from their inert state in the environment it is essential that viruses can efficiently recognize and bind to appropriate host cells. Having achieved this specific association, the virus must have mechanisms to enable the genome to be introduced to the interior of the cell. This requires breaching cellular membranes and is achieved by markedly different mechanisms in different viruses. Once internalized into the cytoplasm or nucleus, macromolecular synthesis is initiated from the viral template. In most cases the first event is the synthesis of mRNA, although in some RNA viruses the genomic RNA can act directly as mRNA. The mRNA is transcribed by host or viral enzymes, depending on the virus type, and is usually post-transcriptionally modified, again by host or viral enzymes. Viral protein synthesis is entirely dependent on host-cell machinery, although many viruses have mechanisms to subvert the process to their own advantage. The viral protein products are frequently post-translationally modified, again by host or virally encoded enzymes. Virus genome replication frequently occurs in discrete compartments within the cell that are assembled during the infectious process and often involve massive reorganization of the intracellular structure. The assembly of new virus progeny is the penultimate stage of virus replication. It can occur by the spontaneous association of the structural components of the virus in a relatively simple mass action process or, in the case of the larger viruses such as herpesviruses, may involve complex multistep pathways requiring the assembly of

templates constructed from proteins that are not incorporated into the mature virus particles. Finally, the progeny virus particles must be released from the infected cell. This can occur by a variety of methods ranging from destructive lysis of the cell to the budding and release of new particles at the cell surface.

As an essential accompaniment to the replication process, many viruses utilize a range of mechanisms to divert or inactivate the innate and adaptive immune responses which would otherwise terminate viral replication either directly, or indirectly through the destruction of the infected cell. In the smaller viruses, these functions are often associated with multifunctional proteins that are also involved in viral replication. With the larger DNA viruses a significant proportion of the genome is devoted to the encoding of a wide range of proteins whose roles are specifically concerned with diverting the immune response mechanisms.

INITIATION OF INFECTION

The roles of virus particles

The essential roles of the virus particle, or virion, are to protect the viral genome from damage in the extracellular and extrahost environments, to efficiently bind to new host cells and to facilitate the delivery of the genome into the new host cell. These requirements place important and sometimes apparently conflicting demands on the structure and function of the virion. To protect the genome the particle must resist, as far as possible, the chemical and physical insults it is likely to encounter in the extrahost environment. It must, therefore, be a stable structure. However, this stability must be reversed during the infection process to allow release of the genome and its delivery into the new cell. In order to accommodate these diverse functions, triggering systems are frequently built into virus particles such that conformational changes occur during the initiation of infection that convert the virion from a protective capsule into an efficient delivery machine. Although these principles apply widely across the virological spectrum, there is great variety in the ways in which they are achieved.

Virus attachment

The first event in the infection process is the attachment of the virus particle to a receptor molecule at the surface of the new host cell. This involves the specific recognition between specialized receptor-binding domains on the virion surface and receptor molecules on the cell. In many cases the specificity of this interaction is a major determinant of cell tropism and can, therefore, be an important factor in defining the pathogenesis of infection. Many cell surface molecules are utilized as receptors for different viruses. In some cases viruses bind to rather nonspecific features of host-cell envelope proteins, for example, sialic acid residues. In other cases the virus/host cell receptor interaction is highly specific and is a major determinant of host and tissue tropism.

For enveloped viruses the first receptor binding protein to be studied in atomic detail was the hemagglutinin (HA) protein of influenza virus (Wiley and Skehel 1987). It is a type 1 envelope protein with a large, highly glycosylated ectodomain exposed at the surface of the virus particle, a single transmembrane domain and a short C terminal domain located on the inside of the viral envelope. The monomeric HA protein trimerizes to form functional spikelike projections from the surface of the virus (Figure 1). Each trimer has a stalklike domain adjacent to the membrane and terminates in a globular domain. This globular head contains the receptor binding pockets, three per HA trimer, which engage sialic acid moieties on cell receptor glycoproteins. The specificity for sialic acid is defined by the amino-acid side chains lining the receptor-binding pocket. Although these amino acid residues are necessarily highly conserved across the influenza subtypes, their location within a pocket renders them invisible to antibody recognition. This feature allows the virus to evolve variants able to escape immune responses directed against antigenic sites distributed around the globular domain of HA, while retaining the ability to utilize sialylated host-receptor glycoproteins. A second envelope glycoprotein of influenza virus is the neuraminidase protein. This removes sialic acid residues from host glycoproteins and is important for the release of progeny virus from infected cells which would otherwise be sequestered to membrane surfaces via their HA proteins.

Another virus receptor-binding protein that has received much attention is that of the human immunodeficiency virus (HIV). As for influenza virus, the HIV receptor-binding protein is a type 1 membrane glycoprotein which binds to a 60-kDa envelope glycoprotein, CD4, present at the surfaces of helper T cells and macrophages. The extreme specificity of this recognition process is one of the major factors responsible for the restriction of HIV infection to the higher primates. Although CD4 acts as the primary receptor for HIV, secondary receptors, the chemokine receptors, CXCR4 and CCR5, are engaged post-CD4 binding and are essential for completion of the infection process. Adaptation to either of these coreceptors dictates the cell tropism of different strains of the virus.

Utilization of multiple receptors during the infection process is seen in a wide range of viruses. Several viruses, herpesviruses for example, bind to heparin sulfate found ubiquitously linked to gangliosides at cell surfaces. This nonspecific initial binding probably functions as a means to concentrate virus particles at cell surfaces prior to engagement of more specific receptors

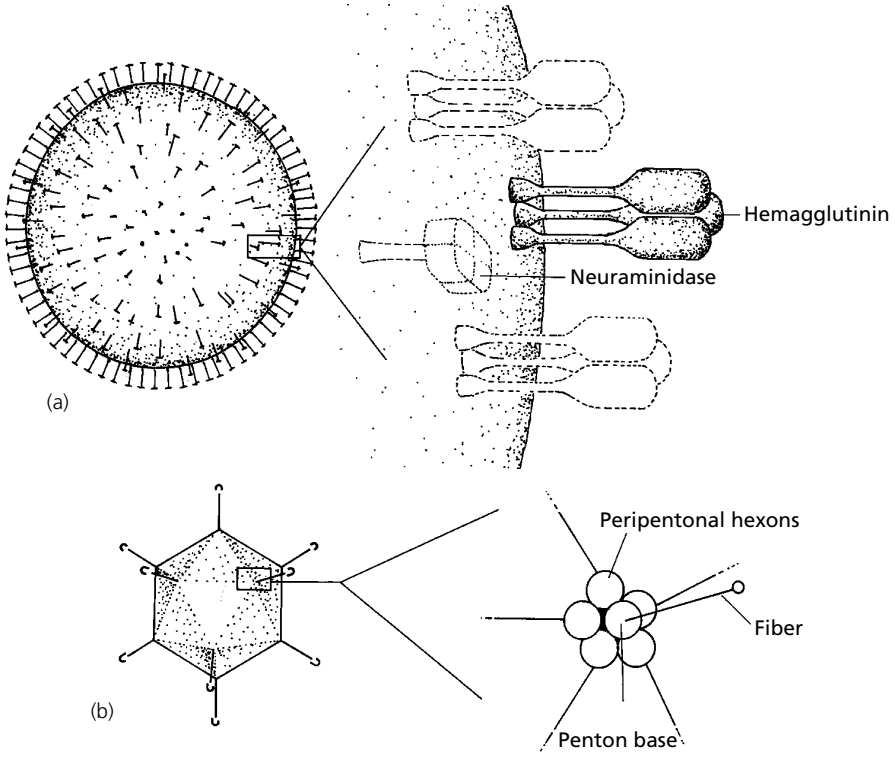

Figure 1 *Attachment of viruses to host cells.* **(a)** *Influenza is shown as a typical example of an enveloped virus. The virus membrane is decorated with the trimeric hemagglutinin protein (HA) and the tetrameric neuraminidase protein (N). The cellular receptor binding region of HA is located at the membrane distal 'head' domain of the molecule and associates with sialic acid residues on cell proteins. The N protein is required for release of virus at the end of the replication cycle.* **(b)** *Adenovirus is shown as an example of a naked, nonenveloped virus. The primary receptor binding domain of the virus is located in the knob protein at the ends of the 12 fibers situated at the vertices of the icosohedral capsid. Following initial attachment, conformational changes in the fiber bring the particle closer to the cell surface where a second receptor, an integrin, engages at a site on the penton base. This second receptor interaction is essential for completion of the infection process. The receptor-binding domains of most viruses protrude from the particle surface but in some cases, poliovirus for example, the receptor-binding region of the virus is buried within a groove or 'canyon' in the capsid.*

necessary to complete the infection process. In a further example, the primary receptor binding feature of the nonenveloped adenoviruses is a knob structure located at the tip of long fibrous proteins projecting from the 12 vertices of the icosahedral virus particle (Figure 1). After binding of the knob to the primary receptor, the fiber distorts to bring the virus particle closer to the cell surface and allows the engagement of a second receptor as a necessary component of the infection process. The secondary receptors are members of the integrin family, a large family of heterodimeric membrane glycoproteins involved in a range of cellular recognition events. The engagement with integrin molecules initiates viral internalization within endosomes, which is a necessary step in the infection process.

VIRUS ENTRY

All viruses must gain entry to the host-cell cytoplasm and/or nucleus to initiate the infection process. In some cases this occurs directly at the plasma membrane, for others it is subsequent to internalization into endosomes or other invaginated vesicles. However, the crucial step is the transport of the viral genome across a cellular membrane, for even within endosomes the virus is still topologically outside the cytoplasm of the cell. For enveloped viruses the problem of gaining entry is conceptually simple. Fusion of the envelope of the virus with the cell membrane will result in delivery of the viral content directly into the cytoplasm. For nonenveloped viruses, the problem is more complex and different viruses have either evolved mechanisms for the disruption of membranes within vesicles, such as endosomes, to allow the virus particle access to the cytoplasm or they can form pores in cell membranes, which allow the nucleic acid alone to enter the cytoplasm.

Influenza is the classic example of entry of an enveloped virus via endocytosis. The binding of the virus to host-cell receptors initiates the process of endocytosis which draws the attached virus particles into clathrin-coated pits. These pits invaginate into the cell and are pinched off to form endosomal vesicles or endosomes. These migrate within the cytoplasm towards the nucleus, becoming increasingly acidified by the action of proton ATPase during the process. The reduced pH within endosomes triggers conformational changes in HA and

facilitate a crucial step in the infection process of enveloped viruses, that of membrane fusion (Weissenhorn et al. 1999). The globular head domains of the HA molecules move away from the central stalk region, which is reorganized into an elongated alpha helical structure terminating in a short hydrophobic region, the fusion peptide. Insertion of this peptide into the endosome membrane and subsequent conformational change brings the viral and cellular membranes into close proximity and initiates the fusion of the two membranes, although the precise details of this process are only now beginning to be understood (Figure 2). A key feature of this process is that the fusion peptide is sequestered within the stalk region of the HA trimer and only becomes exposed to facilitate the fusion process following acid-induced reorganization of the structure of the protein within endosomes. Another important feature of the mechanism is that the HA protein is synthesized as a precursor protein, HA0, which must be activated by a maturation cleavage, carried out by a host cell protease, furin, into HA1 and HA2. This cleavage leaves the fusion peptide at the N terminus of HA2 and allows the molecule to undergo acid-induced rearrangement.

The example of influenza illustrates the basic principles that underlie the infection mechanisms of many viruses that gain entry to the cytoplasm via endocytosis (Klasse et al. 1998; Bentz and Mittal 2000). Quasistable components of the virus undergo acid-induced conformational rearrangements to expose specialized features that interact with and modify cellular membranes. Recently the entry mechanisms of the alphaviruses and flaviviruses, two families of enveloped positive-strand viruses, have been elucidated. Although there are important differences from influenza HA in the details of the process, the underlying principles are similar. The surface glycoproteins of these viruses are highly ordered and their interactions define the icosahedral symmetry of the virus particle, in contrast to influenza in which the HA spikes are randomly distributed in the envelope. In addition, the fusion peptide is located internally within an envelope glycoprotein rather than at the N terminus. Marked rearrangements of the envelope proteins result in the insertion of this peptide into the host membrane and draw the host and virus membranes into close apposition to facilitate their fusion, as in the influenza case.

In the examples quoted above, the switch to a fusogenic form of the virus is triggered by acidification in endosomes. Other viruses achieve the same state following receptor or coreceptor engagement. In these cases the acid pH found in endosomes is not necessarily required for virus entry and fusion may occur at the plasma membrane. HIV is a well-studied example of this mechanism in an enveloped virus. As for influenza virus, the receptor binding glycoprotein of HIV is produced as a type 1 envelope protein, gp160, which is subsequently processed into a membrane-associated C-terminal domain, gp41, and a major receptor binding component, gp120. Engagement of the virus with its primary receptor, CD4, occurs via an interaction with gp120. Subsequent engagement of a secondary or coreceptor, which can be CVCR4 or CCR5 depending on the cell tropism of the virus, triggers the conformational changes in gp41 required to convert the protein into a fusogenic state.

Although membrane fusion per se is clearly not an option for nonenveloped viruses, the principle of acid or receptor-induced triggering of conformational changes

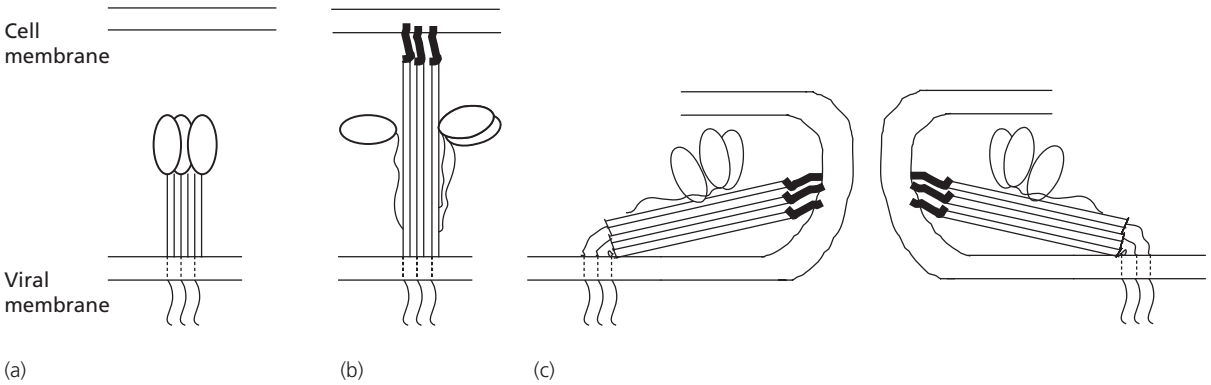

Figure 2 *The cell entry process of enveloped viruses. Enveloped viruses gain entry to host cells via fusion of the viral and cellular membranes, thus making the contents of the viral envelope contiguous with the cytoplasm. The diagram illustrates the mechanism for influenza virus, but the principles appear to be the same for most, if not all, enveloped viruses.* **(a)** *The virus attaches to the cell by interactions between HA and proteins in the plasma membrane.* **(b)** *Conformational changes are induced in the HA molecules and result in the exposure of a hydrophobic 'fusion peptide' sequence, which is projected from the viral membrane and inserts into the cell membrane. In the case of influenza these changes are induced by the reduction in pH in endosomes. Similar conformational changes may be induced by other mechanisms, such as engagement of a second or coreceptor in some viruses.* **(c)** *Further conformational changes result in the cellular and viral membranes being brought into close proximity, the reorganized HA being anchored in the cell membrane by the fusion peptide and the viral membrane by the transmembrane domain. This results in membrane fusion, although the details of the final process are not fully understood.*

associated with the infection process still apply. For some viruses, for example the adenoviruses and the reoviruses, the entry process involves the disruption of endosomal membranes so that the virus particles within the vesicles become confluent with the cytoplasm. Although the mechanisms involved in this membrane disruption process are not fully understood, they are clearly preceded by conformational changes in the virus particles.

In many, if not all, picornaviruses only the viral RNA is introduced into the cytoplasm, the proteins of the virion remaining topologically on the outside of the cell. The mechanisms involved are best understood for poliovirus. The receptor for the virus is a type 1 glycoprotein known as CD155 or PVR (poliovirus receptor) and binds within a groove, known as the canyon, which surrounds the fivefold axis of the icosahedral virus capsid. Engagement of the receptor induces major changes in the virus particle, which results in the externalization of the N termini of the VP1 protein and the loss of the small myristoylated internal protein, VP4. The N-terminal amino acid sequence of VP1 has the potential to form an amphipathic helix and this entry intermediate particle associates with membranes via this sequence. Both the externalized N termini of the VP1 proteins and the released VP4 protein are thought to form channels or pores through which the RNA is transported into the cytoplasm (Hogle 2002). Similar mechanisms probably apply to other picornaviruses but studies with these are less well advanced.

Having breached the membrane and gained entry into the cytoplasm different viruses distribute to different compartments within the cell. Many viruses replicate within the cell nucleus, for example, most DNA viruses and influenza virus. Transport to the nucleus is achieved by association with the microtubule system within the cytoplasm and traveling along this in a retrograde direction to the perinuclear region (Sieczkarski and Whittaker 2002; Greber and Fassati 2003). Either the internal contents of the virus, the genome, and associated proteins, migrate into the nucleus or, as in the case of hepatitis B virus the entire nucleocapsids are transported through nuclear pores.

VIRUS GENE EXPRESSION

As for their strategies of genome organization, viruses have adopted a wide range of mechanisms for gene expression and, of course, the two factors are frequently related. These properties of viruses form the basis of the Baltimore classification of viruses (Baltimore 1971) (Figure 3).

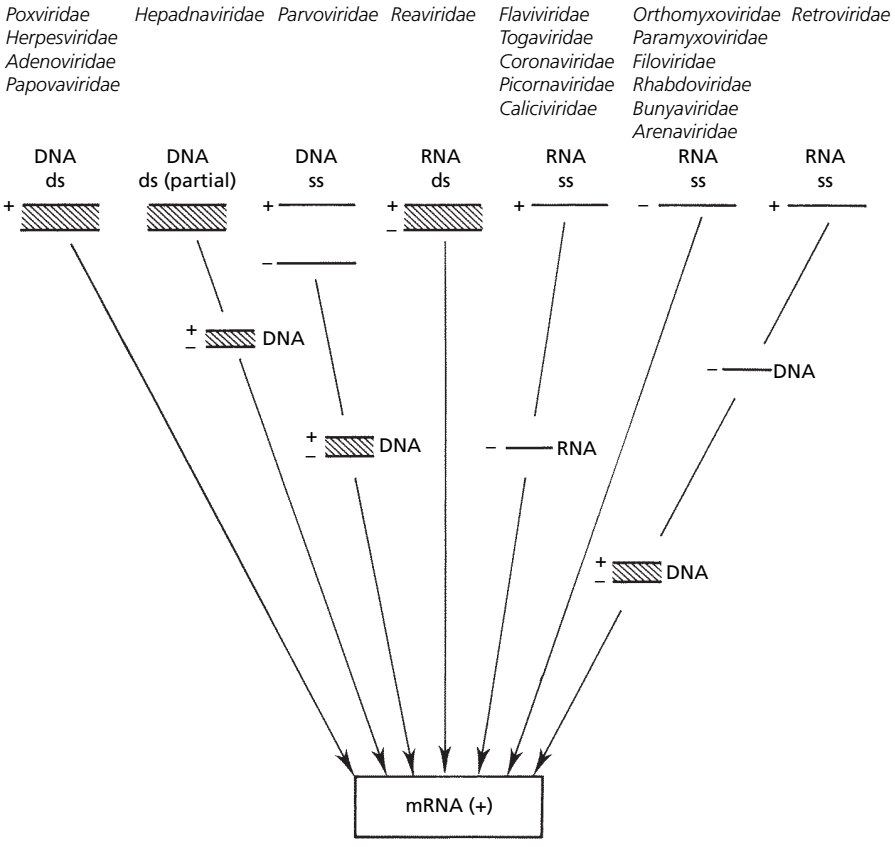

Figure 3 *Grouping of viruses by genome composition and pathway of mRNA synthesis.*

Most DNA viruses utilize the basic cellular enzymes for transcription of their mRNAs, although they usually exert strong controls over the specificity of gene expression to their own advantage. A notable exception to this generality is the case of poxviruses, which replicate within the cell cytoplasm and are thus obliged to incorporate virally encoded transcription enzymes in the virus particle.

RNA viruses, on the other hand, invariably encode their own RNA-dependent RNA polymerases (RdRp), which function both as transcriptases to produce mRNAs and as replicases to produce progeny genomes. This is an absolute requirement for RNA viruses as RdRp enzymes are rare in normal cells. For positive-strand RNA viruses, the viral genome functions directly as a mRNA and is translated to produce the virally encoded proteins, including the RdRp. For this reason the naked RNA of positive-strand viruses is itself infectious if appropriately introduced into cells. As a consequence reverse genetics, the in vitro manipulation of cloned cDNAs of viral genomes to introduce specific mutations and their recovery as virus from in vitro transcribed RNA copies, was first developed for positive-strand viruses. This technique has been an immensely useful research tool for dissecting the molecular details of virus replication. Negative-strand viruses, on the other hand, must incorporate the RdRp within the virus particle. This is essential for the transcription of mRNAs required to initiate viral protein synthesis.

DNA viruses

The majority of double-stranded DNA viruses, for example *Papovaviridae*, *Herpesviridae*, and *Adenoviridae*, use the transcription machinery within the host nucleus to synthesize their mRNAs. The initiation of transcription is strictly controlled, often on a temporal basis, in order to co-ordinate the production of viral proteins and to afford maximum advantage to viral biosynthesis. However, some double-stranded DNA viruses, notably the poxviruses, replicate within the cytoplasm. As the host enzymes responsible for transcription and replication are located entirely within the nucleus, these viruses encode all of the enzymes required to carry out these functions. Another important consequence of the cytoplasmic lifestyle is that the enzymes required for mRNA synthesis must be encapsidated along with the viral genome into virus particles in order to initiate the infection process. Consequently, the naked genomes of these viruses are non-infectious when introduced into cells, in contrast to the genomic DNA of nuclear replicating double-stranded DNA viruses.

Single-stranded DNA viruses, such as the *Parvoviridae* must be converted into a double-stranded form before they can act as templates for the synthesis of mRNA. This is accomplished by host polymerase enzymes.

RNA viruses

The genomes of the single-stranded positive-sense RNA viruses, which include the *Picornaviridae*, *Togaviridae*, *Flaviviridae*, *Caliciviridae*, and *Coronaviridae*, are infectious in the absence of any other viral components. The RNA is translated into viral proteins immediately upon delivery into the host cell and the same molecule must function as template for both protein synthesis and, subsequently, for genome replication. The *Picornaviridae* and *Flaviviridae* RNAs are translated into single polyproteins, which are then proteolytically processed into mature protein products, whereas the other viruses produce subgenomic mRNAs. There is a variety of strategies for the production of subgenomic RNAs and their purpose is to control the relative amounts of viral proteins produced; structural proteins generally being required in greater amounts than nonstructural proteins (Figure 4).

The single-stranded negative-sense RNA viruses replicate in the cytoplasm. The RNA alone is not infectious as the production of mRNA requires the function of the viral RdRp, an enzyme not found in host cells. The RdRp functions as both transcriptase, to produce viral mRNAs, and as a replicase, to produce progeny genomic RNA later in the growth cycle. It is introduced into the cell along with the genomic RNA as a ribonucleoprotein complex. The mRNAs encoding the different viral proteins are separately transcribed, thus allowing for differential control of the relative amount of each that is produced. In the segmented negative-sense RNA viruses most of the viral genes are encoded on separate RNAs and a successful infection requires the simultaneous delivery of all segments. Each functions as a separate template for transcription and replication. The segmented negative-sense RNA viruses, such as the *Orthomyxoviridae* and the *Bunyaviridae* employ a mechanism known as ‘cap snatching’ to initiate transcription of their mRNAs. In this process short oligonucleotides are cleaved from the 5′ ends of host mRNAs, including the 5′ terminal CAP structure, and are used to prime transcription of the viral mRNAs. This process occurs in the host-cell nucleus and all of these viruses require a functional host-cell nucleus for their replication.

The double-stranded RNA viruses all have segmented genomes which range in number from two to 11. The double-stranded genomic RNAs are retained within the nucleocapsids at all times during the replication cycle and the particles function as complex transcription machines, ejecting single-stranded RNAs, which can function both as mRNAs and as templates for new viral progeny. Double-stranded RNA is a powerful inducer of innate immune responses, such as the interferon response, and the strategy of these viruses of sequestering the double-stranded genome within particles has

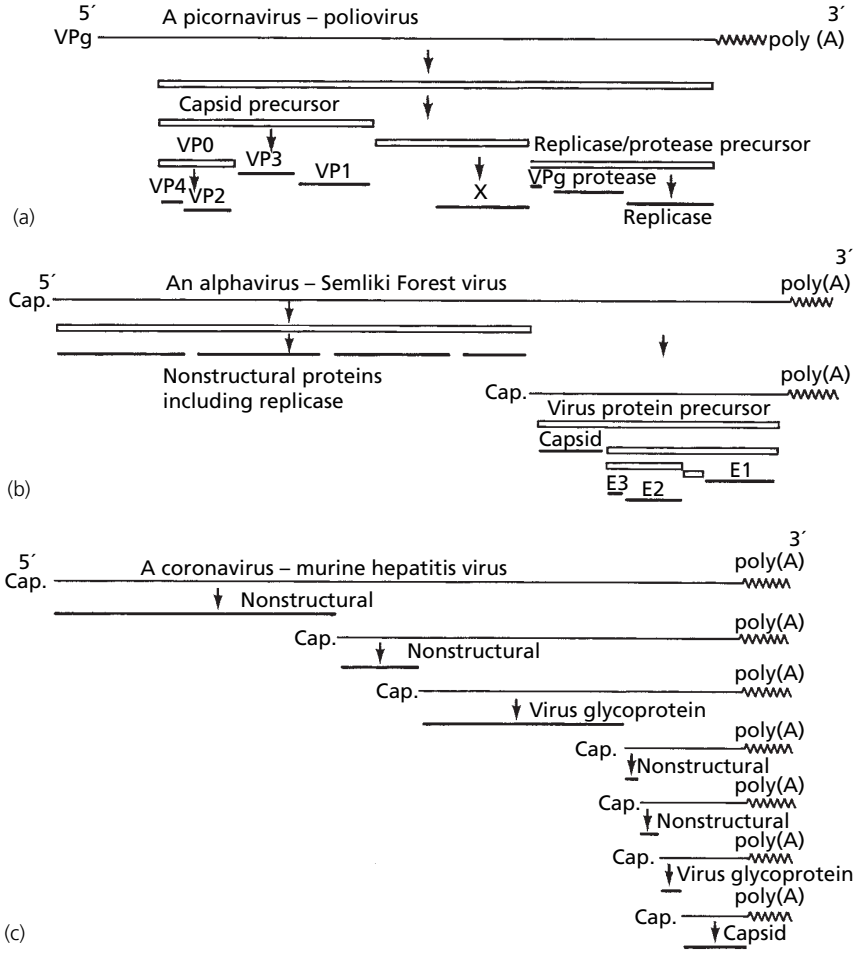

Figure 4 *Gene expression strategies of positive-strand RNA viruses.* **(a)** *The picornaviruses, such as poliovirus, translate their genomes as a contiguous polyprotein, which is subsequently proteolytically processed into a series of intermediate and mature proteins. Many of the intermediate products have functional roles different from those of the final cleavage products. The open reading frame for the polyprotein occupies most of the viral sequence and translation is initiated from a highly structured sequence within the 5′ untranslated region of the genome.* **(b)** *The genomic RNA of alphaviruses also functions as a mRNA to produce a polyprotein, but in this case only the nonstructural proteins responsible for virus replication are derived from the virus RNA. During replication, a subgenic mRNA encoding the structural proteins is produced in abundance. The nonstructural protein precursor is processed by viral protease and the structural proteins are processed by cellular enzymes.* **(c)** *The production of subgenomic mRNAs is most evident in the coronaviruses, which synthesize a nested set of subgenomic mRNAs each of which, with minor exceptions, is translated into a single viral protein encoded in the 5′ portion of the sequence.*

obvious relevance for avoidance of these defense mechanisms. The strategy requires that the viral entry mechanism allows for the transport of the entire nucleocapsids into the host-cell cytoplasm and also that there is an accurate packaging mechanism to ensure the incorporation of a full set of genome segments into at least the majority of virus particles.

Reversiviruses

The identification of reverse transcriptase broke the central dogma that stated that information transfer progressed from DNA through RNA to protein and could not travel back up this chain. The reverse transcriptase polymerase is able to copy an RNA template into DNA and its discovery was of great benefit to the expanding field of molecular biology, as well as being of fundamental importance in understanding the life cycle of many significant viruses. Reverse transcriptase is integral to the replication strategies of both the *Retroviridae* and the *Hepadnaviridae*, but it functions at different stages in the life cycles of these two families of viruses. Retrovirus particles contain genomic RNA and are haploid, each particle containing two template molecules. Immediately after infection the encapsidated reverse transcriptase copies the virion RNA into DNA, using a host tRNA as primer. The resulting double-stranded DNA is integrated into the host genomic DNA from where virus-specific mRNAs are transcribed by host transcription mechanisms. In the hepadnaviruses,

such as hepatitis B virus, the timing of the reverse transcriptase function is reversed. In these viruses a pregenomic RNA molecule is encapsidated along with the viral polymerase. This then copies the RNA into an incomplete double-stranded circular DNA molecule within the nucleocapsid particle. Upon infection of a new host cell the partial circular DNA is completed and functions as a template for host transcriptase, but without the requirement for integration into the host genome.

mRNA synthesis

The majority of viral mRNAs conform to the paradigm for cellular mRNA structure and function. However, there are some notable exceptions, as will be discussed later. Cellular mRNAs are produced in the nucleus where they undergo a number of processing events before they are exported to the cytoplasm to program protein translation. Viruses that replicate in the nucleus have access to the host-cell mRNA modification machinery, whereas cytoplasmic replicating viruses must encode for the required functions within their genomes. Because of their small size and relative ease of manipulation, viruses have been invaluable agents for the elucidation of many of the molecular mechanisms involved in synthesis, processing, and functioning of mRNAs.

The main steps involved in the synthesis and maturation of host-cell mRNAs can be summarized as follows:

- Initiation of transcription by DNA-dependent RNA polymerase at a defined position on the genomic DNA. The location of the initiation site is defined by promoter binding sequences which are crucial for the control of the nature and amounts of mRNA transcripts produced.
- The cap structure, a modified guanosine residue, is added to the 5′ terminal nucleotide of the nascent transcript.
- The 3′ end of the transcript is extended with a polyadenylate (poly(A)) sequence.
- For most mRNAs, the primary transcript is far longer than the final mature mRNA that is exported to the cytoplasm. A complex series of cleavage and ligation events remove parts of the initial transcript known as introns and splice the remaining exons into the final mRNA.

Capping and polyadenylation

All cellular mRNAs terminate at the 5′ end with a modified nucleotide, 7-methylguanylate (m^7G) which is linked to the 5′ terminal encoded nucleotide of the mRNA by an unusual 5′–5′ linkage. Specialized transferases are responsible for the methylation of the guanyl nucleotide and the addition of the modified nucleotide to the mRNA. The cap is important for maintaining mRNA stability in the cytoplasm and in the process of initiation of protein synthesis. It is recognized by the cap binding protein, eIF4E, which is one of the components of the eukaryotic translation initiation factor eIF4. The other members of this complex are eIF4A, which may be an RNA helicase and is involved in the migration of the completed complex along the mRNA and eIF4G, which functions as a scaffolding protein to link the cap, via eIF4E, to further initiation factors including the 40S subunit of the ribosome. Once assembled the entire preinitiation complex migrates in a 3′ direction until a translation initiation codon (AUG) in a favorable sequence context is encountered. At this point some initiation factors are released, the 60S ribosomal subunit is engaged to assemble the full 80S ribosome and translation begins.

The 3′ ends of most mRNAs also possess a common feature, the poly(A) tract. This again is nontemplated and is up to 200–250 nucleotides in length. As for the cap, the poly(A) tract is important for mRNA stability within the cell. It is also recognized by the poly(A) tract binding protein (PABP) which, in addition, binds to regions of the initiation factor eIF4G. This interaction effectively results in the circularization of the mRNA and is thought to increase RNA stability and the efficiency at which reinitiation of translation on the mRNA occurs.

Thus, capping and polyadenylation are very important for mRNA function and, with some notable exceptions discussed below, are features of viral, as well as host mRNAs. Viruses that replicate in the nucleus generally make use of the host biochemical machinery present in that compartment of the cell to carry out the capping and polyadenylation modifications of their mRNAs. However, viruses that replicate within the cytoplasm need to supply these functions in addition to the polymerase activity of their transcriptase. The poxviruses are very large DNA viruses that replicate in the cytoplasm and encode all the enzyme functions required for capping and polyadenylation. The best studied member of the family, vaccinia virus provided much of the earliest detailed information on the biochemistry of the capping process. Interestingly, the capping enzyme of vaccinia has multiple roles in the replication of the virus as it also functions as a transcription termination factor of early mRNA synthesis and as an initiation factor in intermediate gene transcription. This illustrates a common theme in virology that virus products often have multiple functions, presumably in the interests of genomic economy. For most of the cytoplasmic replicating RNA viruses, the capping and polyadenylation functions are additional functions associated with the viral RdRp. The importance of this multifunctional polymerase is reflected in the fact that it is often the largest gene encoded by these viruses and accounts for 20 percent of the genome in picornaviruses and 63 percent in rhabdoviruses viruses.

The poly(A) tract found at the 3′ end of most mRNAs is added by the transcriptase in a stuttering function initiated by specific signal sequences. The most important of these is the conserved consensus sequence AAUAAA situated some 15–30 nucleotides upstream of the polyadenylation site.

Some viruses, such as the *Picornaviridae* and the *Pestivirus* and *Hepacivirus* genera of the *Flaviviridae* have dispensed with the requirement for a cap structure and adopted a different strategy for protein translation as outlined below. In the *Picornaviridae*, the *Flavivirus* genus of the *Flaviviridae* and the *Togaviridae* the poly(A) tract is templated in the genomic RNA while some viruses, the hepaciviruses, pestiviruses, and viruses of the *Reoviridae* family do not have polyadenylated mRNAs.

Control of transcription

The function and nature of every cell is a consequence of it transcription and translation activities, i.e. its gene expression profile. Consequently, the control of transcription and translation are crucial to normal cell function and the same applies, to a greater or lesser extent, to virus gene expression. The three major classes of cellular RNA transcripts, transfer RNAs (tRNA), ribosomal RNAs (rRNA), and messenger RNAs (mRNA) are synthesized by different polymerase enzymes; tRNA by pol I, rRNA by pol III, and mRNA by pol II. It is the profile of mRNA transcripts produced by pol II that defines the gene expression patterns within cells. The rate of transcription of each gene is controlled by specific recognition sequences, termed promoters, which are located at defined distances upstream of the coding sequence for that gene. Promoters are located within 100 base pairs of the start site for transcription of a gene and define the precise position at which transcription of the gene sequence into mRNA is initiated and the frequency of transcription initiation. Within this region two or three short sequences are the most important recognition elements. The most highly conserved of these is the TATA sequence, often referred to as the TATA box. This is located about 30 bases upstream of the initiation site for transcription and artificial movement of this sequence shifts the start site for transcription accordingly. Removal of the TATA box prevents or greatly reduces transcription frequency. Other sequences that are frequently seen in the promoter region are CCAAT and GC boxes. Promoters consist of canonical sequences, like the TATA box, which are involved in DNA-dependent RNA polymerase recognition and specialized sequences that are gene specific and are recognized by highly specific binding proteins, transcription factors, that form complexes with the transcriptase and define the specificity of transcription initiation. Thus the control of gene expression via transcription is dictated by the levels and activities of a range of transcription factors within the cell. The presence and activity of different transcription factors can vary in response to signals received by the cell via a plethora of receptors and transmitted to the transcription machinery in the nucleus by a cascade of biochemical modifications of intermediary signalling molecules. Some of these signalling pathways are initiated by the recognition of viral infection within the cell, e.g. by the presence of double-stranded RNA, and result in the induction of a suite of antiviral response proteins. Many viruses have evolved mechanisms to avoid these responses by either interfering with the cellular signalling pathways or by resisting the inhibitory effects of the induced antiviral response mechanisms.

Another level of transcriptional control is provided by a further series of sequence elements known as enhancers which are present in regions flanking genes. Enhancer sequences are longer than promoters and can be located at considerable distances from the genes whose expression they influence. Moreover they are orientation independent and can be found either upstream or downstream of genes. They are typically 200 nucleotides in length and clearly play important roles in DNA viruses as they are highly conserved and the longest known enhancer sequences have been described in viruses. For example, enhancers in cytomegalovirus range from 400 to 700 nucleotides in length and include the strongest known. They function by altering the structure of DNA to make it more accessible to transcription factors.

DNA viruses that replicate in the nucleus utilize the host pol II-dependent transcriptase activities to express their own genes. DNA viruses that replicate in the cytoplasm, such as the poxviruses, have no access to the host machinery and need to encode their own transcriptase enzymes. In order to initiate the infection process these enzymes must be introduced into the host cell within the virus particle. For this reason the DNA alone of poxviruses is not infectious, in contrast to DNA of herpesviruses and adenoviruses. Sequence analysis of the core polymerase genes of a range of viruses shows considerable conservation between these and host enzymes. In fact, there is significant conservation of certain sequences across the whole biological spectrum from bacteria through to plants and animals. The most striking of these is the triplet GDD which is found in DNA-dependent RNA polymerases, RNA-dependent RNA polymerases, and reverse transcriptases and is involved in the co-ordination of catalytically active magnesium atoms. Other regions of sequence conservation are distributed throughout the polymerase sequences interspersed between more variable regions. Determination of the molecular structures of an ever-increasing range of polymerase enzymes at atomic resolution by X-ray crystallographic techniques is providing insights into their structure/function relationships. From these studies the subdomain components of the enzyme

structures are resolved and clarify the patterns of sequence conservation and variation that characterize polymerases from different sources. In addition to the core RNA polymerase enzyme, the functional transcriptase is a complex of a number of proteins with ancillary roles in the transcription process, such as helicase function for unwinding the template during the copying process. The transcriptase complex of vaccinia virus, for example, comprises a total of seven proteins with a combined molecular weight of 500 kDa.

All RNA viruses are transcribed using virus-encoded enzymes. This is because RdRp activities are not available in normal host cells and must be provided by the virus genome. RNA viruses typically have smaller genomes than most DNA viruses and a significant proportion of their genome encodes the RdRp. For example, 19.5 percent of the poliovirus genome, 49.3 percent of the influenza virus genome, 54.5 percent of the Sendai virus genome, and 62.7 percent of the vesicular stomatitis virus (VSV) genome encode this enzyme. RdRps do not have proofreading functions and the replication of RNA viruses is consequently highly error prone. This is likely to be a reason for the small size of RNA virus genomes. Also, for RNA viruses the same polymerase enzyme functions as a transcriptase to produce viral mRNA and as a replicase to produce progeny virus RNA. A wide range of strategies to differentiate the transcriptase and replicase functions exists in RNA viruses, as will be discussed below. RdRp activity was first described and studied in detail for VSV. This is a single-stranded negative-sense RNA virus and encapsidates its polymerase within the virus particle. Removal of the viral envelope with mild detergent releases the ribonucleoprotein core of the virus particle and this is capable of synthesizing viral mRNAs if provided with the four ribonucleotide triphosphate substrates in appropriate buffer conditions. The RdRp component of this functional complex is known as the L protein and has a molecular weight of 241 kDa, comprising 2 109 amino acids. In addition to its function as a polymerase enzyme it also has the enzymatic activities associated with capping and polyadenylation of the mRNA transcripts. In common with the RdRps of other negative-stranded RNA viruses, the VSV L protein can only transcribe mRNAs from a ribonucleoprotein template and is inactive when presented with naked RNA. Thus the transcriptionally active ribonucleoprotein complex comprises the viral RNA genome of 11 000 nucleotides, approximately 1 200 copies of the N or nucleoprotein polypeptide, 500 copies of a phosphoprotein, NS, and 50 copies of the L protein.

Protein encoding and translation strategies

Collectively, viruses have adopted a wide range of strategies for the translation of their genetic information into proteins. The two functional reasons underlying most of the unusual aspects of information transfer in viruses are to maximize the efficiency of information storage in the viral genome and to facilitate control of the expression levels of viral genes. Hepatitis B virus provides a good example of economic storage of protein coding information within a small genome. The circular DNA genome of the virus comprises only 3.2 kbp, but every nucleotide is involved in coding for proteins, most in more than one reading frame.

Eukaryotic mRNAs typically have a 5′ cap structure followed by a short 5′ nontranslated sequence. A complex of translation initiation factors, including the 40S ribosomal subunit, assemble at the cap and migrate along the 5′ nontranslated region until an AUG in a favorable sequence context is encountered, at which point the 60S ribosomal subunit is engaged, the initiation factors are released and translation commences. The optimal initiation sequence for protein synthesis, known as the Kozak sequence (Kozak 1986), is AxxAUGG. In most cases, the translation initiating AUG is the first one encountered by the initiation complex in its migration along the 5′ nontranslated region. Once initiated protein translation proceeds along the mRNA until the ribosome reaches a termination codon near the 3′ end of the message where translation ceases and the ribosome dissociates. Beyond the termination site there is usually a short 3′ nontranslated region terminating in a poly(A) tract. As discussed earlier, there is increasing evidence that the poly(A) tract noncovalently associates with the 5′ end of the mRNA through protein factor interactions and that this pseudocircularization increases the efficiency of mRNA template function.

Although many viral mRNAs conform to this paradigm, there is a fascinating array of exceptions to the norm. These include cap-independent mechanisms for translation initiation, the use of noncanonical initiation codons, proteins encoded in overlapping reading frames, slippage mechanisms to facilitate change of reading frame, RNA editing, and ribosome 'skipping.' In addition, some viruses utilize the normal cellular process of RNA splicing to produce multiple mRNAs from the same genetic sequence, but to an almost profligate degree.

The assembly of a variety of mRNAs derived from a single genomic sequence by splicing mechanisms is restricted to viruses that replicate in the nucleus. In particular, adenoviruses, papovaviruses, and some retroviruses (the lentiviruses, such as HIV) make extensive use of splicing to maximize the information storage and retrieval potential of their genomes (Figure 5). Analysis of the mRNA transcript profile of adenoviruses provided the first evidence for RNA splicing which was subsequently shown to be a universal mechanism in eukaryotic gene expression. In the splicing process internal regions within the primary RNA transcript,

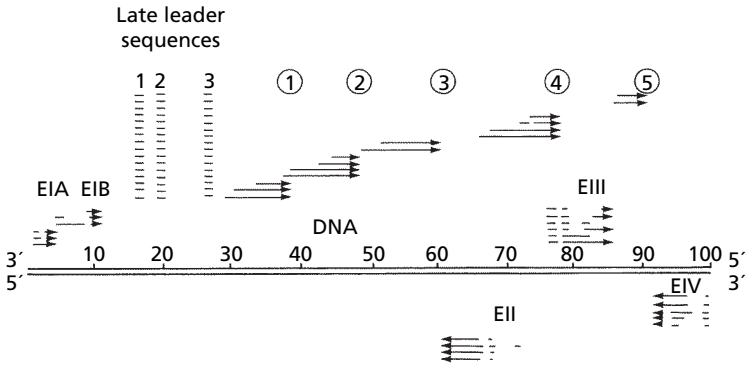

Figure 5 *Gene expression strategy of adenoviruses. Adenoviruses demonstrate complex patterns of gene expression. Different mRNAs are produced at early or late stages of infection and the genetic potential of the genome is amplified by the extensive use of RNA splicing. There are five early gene transcription units (the E transcripts) and another five late gene clusters. The 5′ end of each of the late gene mRNAs has a common tripartite leader sequence comprising three spliced sequences.*

known as introns, are removed and the remaining exon sequences are spliced together by an RNA ligation mechanism. If there are a number of splice donor and acceptor sequences within the primary sequence there is the potential to form an array of mature mRNAs that are recombinant assemblages derived from the same primary sequence. An example of this process is the series of T antigens expressed by viruses of the *Polyomaviridae*. For SV40, early in infection two versions of T antigen, large and small T antigens, are produced from differentially spliced mRNAs. Both mRNAs share a common open reading frame at the start of the transcript. At the end of this common sequence, an intron of approximately 350 nucleotides is removed from transcripts destined to be mRNAs for large T antigen and the open reading frame is maintained through the splice site. The mRNA for the small T antigen is produced by the excision of a smaller intron starting from an alternative splice donor sequence, but terminating at the same splice acceptor site as for the large T antigen. In this case the reading frame is not maintained and translation is terminated at the splice acceptor site. Thus the two transcripts encode unrelated amino acid sequences after the common 5′ region. In other members of the *Polyomaviridae*, further alternative T antigen proteins are produced via the use of additional splice donor/acceptor sites. Most of the RNA viruses replicate in the host cytoplasm and hence do not have access to splicing mechanisms. The *Orthomyxoviridae* are an exception to this and, for example, the mRNAs derived from gene segments 7 and 8 of influenza A virus are produced as spliced variants. In each case one protein is translated from the contiguous unspliced transcript and a different protein is encoded in a spliced version of the transcript. In the spliced mRNA, a sequence a little downstream of the translation start site is removed as an intron and the downstream exon is ligated to the 5′ exon in a different reading frame. Thus, the two proteins share a common short N-terminal sequence, but thereafter are completely different. Additional spliced mRNAs have been demonstrated, but it is unclear whether these are translated into protein products.

Thus, splicing is an important mechanism for deriving the maximum information content from limited genome size. However, this mechanism is not available to cytoplasmic replicating DNA viruses, such as the poxviruses, as no viruses have evolved or acquired the complex enzymatic machinery required to perform the function. In addition, none of the cytoplasmic RNA viruses utilize splicing mechanisms, although these viruses have evolved a number of alternative mechanisms for maximizing genetic storage and control of gene expression and of gaining a competitive advantage over cellular gene expression.

The *Picornaviridae* and the *Pestivirus* and *Hepacivirus* genera of the *Flaviviridae* have evolved a mechanism for the initiation of their protein synthesis that bypasses the normal requirement for recognition of a cap structure by the initiation complex. In these positive-strand RNA viruses the genomic RNA serves as template both for protein translation and for genome replication. They initiate translation via direct association of the initiation complex with a highly conserved RNA sequence located within the 5′ nontranslated region (Figure 6). This sequence comprises about 350 nucleotides in the *Flaviviridae* and is nearer 450 nucleotides in the *Picornaviridae*. In both cases the sequences are predicted to possess a high degree of secondary structure and this has been supported by direct biochemical analysis. In addition there is evidence for a considerable amount of conserved tertiary structure. As these RNA structures are able to initiate translation through their ability to associate directly with the initiation complex and so bypass the requirement for a free, capped 5′ end to the mRNA they have been termed internal ribosome entry sites (IRES). The rational for the possession of IRESs may be that they allow for the presence of highly structured sequences at the 5′ end of the RNA that may be

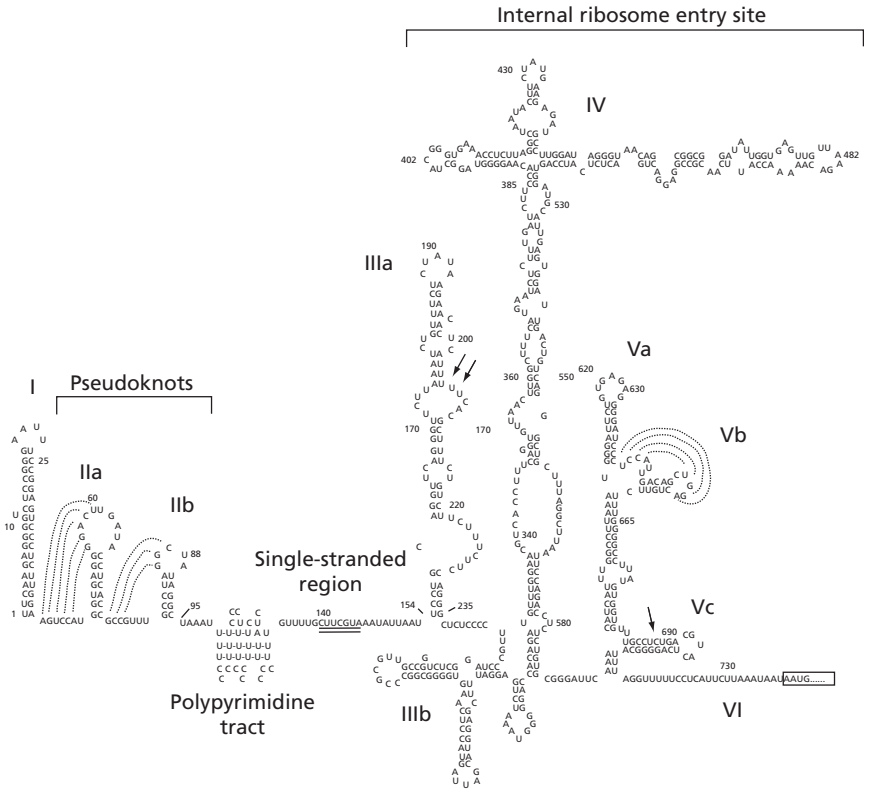

Figure 6 *Proposed RNA structure of the 5′ UTR of HAV. Dotted lines represent potential base-pair interactions in putative RNA pseudoknots; the box indicates the 5′ end of the open reading frame. Stem–loops IIIa–VI (nts 155–735) comprise the IRES. Arrows indicate the site of mutations in cell culture-adapted HAV which facilitate translation. Deletion of the underlined sequence (nts 140–144) leads to a temperature-sensitive phenotype. Figure courtesy of Martin and Lemon (2002).*

important for RNA replication. Such sequences would be inhibitory for the normal process of ribosomal scanning through the 5′ nontranslated region to reach the initiating AUG codon. Whether or not this is the primary raison d'être for IRESs, in several picornaviruses they allow the virus to gain a translation advantage over host mRNAs. The enteroviruses, rhinoviruses, and aphthoviruses encode for proteases that specifically cleave the host translation initiation factor eIF4G. This protein forms a bridge linking the cap recognition protein eIF4E to the rest of the translation initiation complex and its hydrolysis by the viral enzymes effectively negates cap-dependent translation in the cell. Thus, the majority of cell protein translation is inhibited leaving the whole translation apparatus available for the virus. Although the cardioviruses do not cleave eIF4G, their IRESs seem to be highly efficient and can outcompete host mRNA translation and also there is recent evidence that one of the viral proteins, 3A, can associate with nascent ribosomes in the nucleus, resulting in modified organelles that preferentially initiate from the virus IRES. IRESs were first described in viruses but there is increasing evidence that some host mRNAs are translated by the same mechanism. In some cases IRESs have been found to be located within viral mRNAs so as to produce a bicistronic message, translation occurring independently from the 5′ and 3′ portions of the RNA. This has been recognized for some time in certain insect viruses and more recently there is evidence that one of the mRNAs of the herpesvirus, Kaposi's sarcoma virus, is bicistronic, the 3′ open reading frame being translated from an internal IRES.

A number of alternative methods to splicing as a means to maximize information storage have been evolved by viruses that do not have access to splicing machinery. The utilization of alternative translation initiation sites and RNA editing are two methods which are well illustrated by viruses belonging to the *Paramyxoviridae*, for example Sendai virus. Transcripts of the *P* gene of Sendai virus encode three distinct proteins, P, V, and C. The latter is produced as a C terminal nested set of four variant proteins, each initiating at a different in-frame initiation site. The P and C proteins are translated from the primary *P* gene transcript, but initiate at different codons. The frequency at which translation is initiated at different sites is a reflection of their flanking sequence contexts. These include the noncanonical initiation codons ACG and GUG. The *V* gene is produced from a variant transcript in which an extra, nontemplated G residue is added during transcription at a specific RNA editing site. This, of course, alters the reading frame and so the V protein is a hybrid

sequence, the N-terminal part shared with P and the C-terminal region derived from an alternative reading frame. A mechanism of RNA editing is also employed during the replication of hepatitis delta virus. The sole open reading frame of this virus encodes the delta antigen which is produced as a long or short form. The long form is translated from transcripts in which an RNA editing event eliminates a stop codon and allows translation to proceed down the mRNA. The long form has a nuclear location signal not present in the short form and so the two proteins are found in different locations in the cell and this differential distribution is important for the regulation of virus replication and encapsidation to a different stages in the life cycle.

The utilization of alternative reading frames within a single sequence by RNA editing, as illustrated above, requires the transcription of subtly modified mRNA transcripts. Another method of utilizing alternative reading frames has been developed in a number of different viruses and relies on manipulation of the translational rather than the transcriptional machinery. This is ribosome slippage in which specific sequence and structural features within the mRNA induce a slowing and stuttering of translation and result in a proportion of ribosomes changing to a different reading frame, thus producing a hybrid protein as in the case of RNA editing. The normal random error rate in translation of eukaryotic mRNA is in the order of 5×10^{-5} per codon, whereas specific frame-shifting in viral mRNAs can exceed 10 percent. Frame-shifting typically occurs at a homopolymeric sequence of the general structure XXXYYYZ followed a short distance downstream in the mRNA by a pseudoknot (Figure 7). This is a stem–loop structure in which the stem is formed through the hybridization of complementary sequences in the RNA. The sequences within the loop at the top of the stem–loop also hybridize to sequences adjacent to the stem of the stem–loop. This results in the formation of a pseudo-double-stranded structure which impedes the passage of the translating ribosome and facilitates a single nucleotide slippage at the slippery sequence so that a significant proportion of the ribosomes continue translating the message in the −1 reading frame (Deiman and Pleij 1997; Giedroc et al. 2000). For example, ribosome frame-shifting is utilized by viruses in the *Retroviridae* family to control the levels of reverse trancriptase (*pol*) produced in the infected cell. The *gag* and *pol* proteins are encoded by adjacent regions of the viral RNA, but in different reading frames. A frameshifting event occurs at a frequency of about 10 percent to produce a *gag–pol* fusion protein. The mature *pol* protein is then separated from the *gag–pol* fusion protein by a virus-specific proteolytic event.

Another virus-specific variation on the normal process of protein translation has recently been demonstrated for the picornavirus, foot-and-mouth disease virus. This phenomenon has been termed ribosomal skipping and

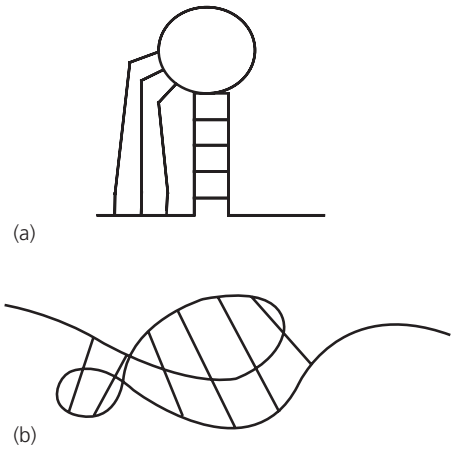

Figure 7 *Ribosome frameshifting: diagrammatic representation of the structure of a pseudoknot. A pseudoknot is formed when there is complementarity between residues in the loop of a stem–loop structure and residues adjacent to the stem–loop* **(a)**. *The actual folding pattern of such a structure is depicted in* **(b)** *and resembles double-stranded RNA. Translating ribosomes pause when encountering such a structure. This, in conjunction with a nearby 'slippery sequence,' leads to a shift in the translational reading frame by a small proportion of the ribosomes.*

occurs when translation continues along the viral RNA, but fails to create a peptide bond at a specific site (Donnelly et al. 2001). This has the same effect as proteolytic processing of the polyprotein translation product of the virus, as occurs at many positions in the sequence, but in addition it permits a level of translational control not otherwise available to viruses that have a single uninterrupted translation product. The skipping event occurs at a position just after the end of the structural protein coding region and involves a 16 amino acid sequence known as protein 2A and is critically dependent on the 2A sequence. It is postulated that termination of translation at this point through a failure to pass through the skipping position could provide a mechanism for excess production of structural proteins at late stages in the virus replication cycle.

As for host mRNAs, the majority of viral mRNAs are monocistronic and in most cases they are subgenomic. In DNA viruses the mRNAs for individual genes are initiated and terminated at specific sequences within the genome sequence and for nuclear replicating viruses the patterns of gene expression can be further complicated by splicing, as discussed above. For the double-stranded and the negative-sense segmented RNA viruses each genome segment generally encodes a single protein. However, in some segmented RNA viruses some genome segments are ambisense, i.e. the virion-sense and complementary-sense RNAs each encode separate proteins. In the single-stranded negative-sense RNA viruses mRNAs for the different gene products are initiated at specific recognition sites within the viral ribonucleoprotein, but are transcribed in sequence from the 3′ end of the viral RNA. The single-strand positive-sense

Togaviridae produce their structural proteins from a subgenomic message representing the 3′ region of the viral genome and in the *Coronaviridae* seven separate subgenomic mRNAs are produced as a 3′ nested set (Figure 4).

Quantitative and temporal control of viral gene expression

DNA VIRUSES

Most viruses have mechanisms to regulate the production of their proteins during infection, but the patterns of control are far more evident in the DNA viruses than the RNA viruses. Some proteins, such as the structural proteins required for assembly of progeny virions, are required in much larger amounts than the enzymatic proteins involved in the replication process and their production is often modulated accordingly. In addition, many viruses produce different proteins at different stages in the infection process. Typically replication proteins and proteins that modulate the host-cell environment to facilitate virus replication are required early in infection while the synthesis of structural proteins is more important at later stages.

The control of protein synthesis in the adenoviruses is well understood and serves as a good example of the principles that apply to many DNA viruses (Figure 5). Transcription is divided into two major phases, early and late. Three of the early genes are transcribed from one of viral DNA strands and two are transcribed from the complementary strand. For all of the adenovirus transcripts multiple alternative initiation, termination, and splicing events result in the production of a variety of proteins from each gene. The first gene expressed when the viral DNA enters the nucleus is E1A. As is often observed with viral proteins the E1A proteins have multiple functions and act as a master gene to both modify the host-cell environment and to orchestrate the transcription of other adenovirus early genes. The E1A proteins have been shown to interact with a large number of host proteins and the functional consequences of all of these interactions are not well understood. However, it is clear that E1A can act as a transactivator to control the transcription of other genes within the early gene cluster via activation of TATA box containing promoters. The activation of these promoters is not through direct interaction with E1A and it does not act as a transcription factor per se. Instead it binds to and modulates the activities of cellular transcription factors and regulatory proteins, such as the TATA box binding protein. It thus facilitates the upregulation of transcription and results in the expression of other early genes. Another important role of E1A is its ability to induce the host cell to progress from a quiescent state into S phase of the cell cycle. This is important for viral replication as the cell environment is far more conducive to DNA replication when in S phase. It achieves this control through its interaction with the cellular protein, retinoblastoma tumor suppressor protein, pRB. This, in turn, controls the activity of E2F cellular transcription factor and when the inhibitory effects of pRB on this transcription factor are released a number of cellular proteins involved in cell cycle progress are produced. Other members of the early gene families of proteins have important roles in negating the antiviral host responses, both innate and adaptive. For example, E1B binds to p53 and inhibits its proapoptotic activity, E3 blocks immune presentation of viral antigens at the cell surface for recognition by cytotoxic T cells and a series of short RNA transcripts, the VA RNAs, inhibit the protein kinase, PKR. This protein is induced as part of the interferon response and in the presence of double-stranded RNA it phosphorylates the translation initiation factor eIF2α, resulting in the inhibition of protein synthesis. The *E2* genes encode the polymerase and terminal protein responsible for viral DNA replication.

Viral DNA synthesis triggers the switch from early to late transcription although the precise mechanism underlying this change is not fully understood. The major late promoter is minimally active before DNA replication and its activity increases enormously thereafter. It has been shown experimentally that this is a *cis*-active phenomenon and so must reflect a change in the physical nature of the DNA template. This may be due to changes in the profile of associated proteins or, more likely, is due to exposure of the promoter region as a consequence of conformational changes during replication. The five late gene families of proteins are all derived from a single long (29 000 nucleotide) transcript through differential polyadenylation site usage and splicing. All of the late transcripts start with a 200 nucleotide spliced region, the tripartite leader. This sequence confers a translational advantage on the viral transcripts at late times in infection. At these times, the eIF4 transcription factor complex is largely dephosphorylated and this results in an inability to scan through mRNAs from the 5′ cap to the translation initiating AUG codon. The tripartite leader allows the ribosome to 'jump' directly from the cap to the initiating AUG without scanning the intervening sequence. An additional translational advantage is gained by the virus late in infection, since at these times newly synthesized host mRNAs are not exported from the nucleus to be translated in the cytoplasm. Viral transcripts are transported to the cytoplasm by a complex of E1B and E4 with cellular factors and this complex may sequester transport factors to the benefit of the viral transcripts and detriment of cellular transcripts.

The general principle of differential expression of viral genes at early and late stages of infection is common to most DNA viruses and many have multifunctional proteins that perform many of the functions outlined above for the E1A protein of adenoviruses. Examples include the T antigens of the papilloma and

papovaviruses and ICP4 of herpes simplex virus, which has a negative effect on the expression of other early genes, but is required for the expression of later genes. Splicing is used minimally by the herpesviruses and not at all by the poxviruses, which lack their own splicing mechanisms and replicate in the cytoplasm away from the cellular systems. These viruses possess some of the largest known viral genomes and express their gene products via a complex cascade of transcriptional events. The series of genes expressed during herpesvirus infection are classified as α, β, and γ proteins and there are further subdivisions of β_1 and β_2 classes. The poxviruses encapsidate both the enzymes required for transcription and the transcription factors required to initiate the process for the early genes. Herpes simplex also encapsidates a protein, VP16, that is involved in the initiation of transcription of its early genes. It forms a complex with cellular proteins Oct1 and HCF-1 and together they promote transcription from viral sequences preceded by the motif TAATGARAT, where R is a purine.

RNA VIRUSES

Positive-strand viruses

The genomes of picornaviruses are single, positive-sense RNA strands of between 7.5 and 8.5 kb in length. The 5′ end is covalently linked to a small protein, VPg, and the 3′ end is polyadenylated. A long 5′ nontranslated region precedes a single open reading frame occupying most of the genomic RNA. This is translated into a single polyprotein product which is cleaved by virus-encoded proteases, both co- and post-translation, into a total of about 12 mature products (Figure 4). The VPg is not required for mRNA function and is normally cleaved from actively translating genomes by a cellular activity. Although no subgenomic mRNAs are produced and there is no mechanism for temporal control of gene expression differential cleavage at the processing sites of the polyprotein are used to increase the complexity of the gene expression profile (Bedard and Semler 2004). Several 'immature' precursor proteins have functions that are different from those of their component 'mature' cleavage products. The genomic RNAs of the flaviviruses are also translated as a continuous polyprotein and, like the picornaviruses the structural proteins are encoded towards the N terminus, the remainder encoding proteins involved in replication. As with the picornaviruses the polymerase protein is located at the C-terminal end of the polyprotein. The flaviviruses are enveloped and their structural proteins are cleaved from the polyprotein by host signal peptidases in the endoplasmic reticulum. The remaining cleavages are carried out by virus-encoded proteases. Although the translation of most flaviviruses is cap-dependent, viruses in the pestivirus and hepacivirus genera use an IRES to initiate translation.

The gene order of the togaviruses differs from the picornaviruses and flaviviruses in that the nonstructural replication proteins are encoded within the 5′ two-thirds of the genomic RNA and the structural proteins are encoded on a separate transcription unit representing the 3′ portion of the genome (Figure 4). The capped and polyadenylated viral RNA is translated on entry into the host cell to produce the polymerase and associated proteins which copy the input RNA into a complementary negative strand. This is transcribed in its entirety to produce progeny viral RNAs or from an internal promoter to produce a subgenomic mRNA representing the 3′ one-third of the genome sequence. This small RNA encodes the structural proteins and is produced in approximately three-fold excess compared with the full length viral RNA. Later in the replication cycle the virion RNA is sequestered by the structural proteins to assemble progeny virions and so the effective concentration of the subgenomic RNA is approximately ten times higher than the viral RNA. As a result, this simple strategy allows for a degree of quantitative and temporal control of the relative synthesis of structural and replication proteins.

The strategy of producing subgenomic mRNAs is carried to its extreme for the positive-stranded viruses in the coronaviruses (Figure 4). A total of six to eight mRNAs, depending on the specific virus, are produced in infected cells and represent a 3′ nested set, the longest being full-length viral RNA. Most of these RNAs are monocistronic and only produce the protein encoded at the 5′ end, the remainder of the RNA remaining translationally silent. Thus, essentially each gene is translated from a separate mRNA. As these are not produced in equivalent amounts this strategy allows for control of the relative amounts of viral proteins produced, although there is no temporal control. Each of the subgenomic RNAs has a common 'leader' sequence at the 5′ end and two mechanisms for their synthesis have been proposed. In one model short RNAs representing the leader sequence are transcribed from the 3′ end of full-length complementary copies of the virion RNA. These then dissociate from the replication apparatus and prime transcription of the individual subgenomic RNAs from conserved sequences present at each intergenic region. In an alternative model, transcription of negative strands is interrupted at the intergenic sequences and resumes at the 5′ leader sequence. Thus a nested set of templates is produced from which the mRNAs are individually transcribed.

Negative-strand viruses

The negative-strand RNA viruses can be broadly divided into those with a continuous genome and those with segmented genomes. Of the single-stranded viruses, VSV is probably the best studied and understood. The obligatory first step in replication is transcription from

the virion ribonucleoprotein by the encapsidated L and P proteins, which together constitute the functional transcriptase, to produce a set of mRNAs. Transcription starts at the extreme 3′ end of the RNA to produce a 47 nucleotide leader RNA terminating in a 5′ triphosphate group. After a short pause, transcription is reinitiated to produce the first mRNA. A pause again occurs at the end of the first transcription unit before transcription is again reinitiated at the start of the next gene on the genome. The order of genes on the genome is *N*, *P*, *M*, *G*, and *L* and this reflects the order of abundance of each protein that is required for virus replication. Each mRNA is capped by the transcription complex and is polyadenylated from a polyadenylation signal present in each short conserved intergenic sequence. Transcriptase complexes dissociate from the template at a frequency of 20–30 percent at each intergenic junction so that the proportion of each mRNA transcript produced is dependent on its position on the genome. The positional frequency of transcription is maintained if the order of genes on the virion RNA is reversed. This strategy allows for a hierarchy of gene expression but not for temporal control of protein synthesis.

Influenza provides a good example of a segmented negative-strand RNA virus. In common with VSV, the viral polymerase is introduced into the cell as part of the ribonucleoprotein viral core. In contrast, it has no capping activity and the viral mRNA transcripts obtain their 5′ caps from host mRNAs by a process known as cap snatching. The polymerase has a nuclease activity that cleaves host mRNAs at a position about 12 downstream of the cap. These heterogeneous fragments are then used to prime the transcription of the influenza virus mRNAs from the individual viral ribonucleoprotein segments. In addition to acting as templates for mRNA synthesis, the input viral RNA segments act as templates for the synthesis of full-length complementary template RNAs. These are subsequently transcribed into progeny vRNA molecules which can act as fresh templates for further mRNA synthesis. Although the production of template RNAs appears not to be, the synthesis of new vRNAs is regulated. This results in inequality in the abundance of different mRNAs and so control of gene expression on a temporal basis.

Double-stranded viruses

The reoviruses are the best studied of the double-stranded RNA viruses. The virus particles are multishelled structures and a core component containing the multisegmented double-stranded RNA genome is introduced intact into the host-cell cytoplasm to initiate infection. At no time during the virus replication cycle is the double-stranded genome exposed to the cytoplasm outside the protein cores. As double-stranded RNA is one of the most potent inducers of host antiviral interferon responses, the sequestering of the genome within particles is probably an important viral defense mechanism. The icosohedral core particles are, in effect, highly ordered transcription machines which synthesize and export RNA transcripts through pores at the fivefold axes of symmetry. The transcripts are capped by the viral transcription apparatus but, unusually, are not polyadenylated at their 3′ ends. The transcripts are full-length copies of the genome segments and function as mRNAs and as templates for progeny double-stranded genome RNAs, when encapsidated within progeny core particles. The genomes of these viruses comprise ten to 12 segments and their high particle:infectivity ratios suggest that there must be very efficient segment sorting in the assembly of progeny virions, but the mechanism for this is not understood. mRNA transcripts are produced in relative abundance according to their segment lengths, thus giving a measure of control of expression levels. In addition, there appears to be differential efficiency of translation of the different mRNA, as well as a general preference for viral gene translation at later times of infection but, again, the mechanisms for this are unclear.

Protein synthesis, transport, and processing

VIRAL EFFECTS ON HOST PROTEIN SYNTHESIS

Cellular and viral mRNAs, alike, are translated into protein by the ribosome, a machine that is too complex to be encoded by viral genomes. In general, ribosomes are not modified in the infected cell, although recent evidence suggests that one of the nonstructural protein products of viruses of the cardiovirus genus of the *Picornaviridae* may associate with nascent ribosomes to specifically facilitate translation of the viral template. However, many viruses have evolved strategies to usurp cell mRNA translation and to avoid some of the cellular antiviral responses at the level of the initiation of protein synthesis. Disruption of the translation of host mRNAs in a way that permits the continuation of viral protein synthesis allows the virus to maximize its own expression and dominate the host machinery. This is a valuable strategy for viruses that induced acute cytolytic infections to produce a maximum progeny burst size and concomitant death of the cell. Some viruses, such as hepatitis C virus, are able to induce persistent infections without cell death. Clearly, disruption of host-cell protein synthesis would be inappropriate for this viral strategy and such viruses must replicate within a competent, surviving cell.

Different viruses have evolved a variety of mechanisms to inhibit cell protein synthesis while allowing their own gene expression to proceed. As mentioned above, many picornaviruses encode proteases that cleave the important scaffolding protein, eIF4G, which connects the cap-binding protein eIF4E to the remainder of the

translation initiation complex. Thus cap-dependent translation is effectively abrogated in the infected cell and the virus overcomes this inhibition by initiating translation via a specialized RNA structure, the IRES. This associates directly with the ribosome and initiation factors without the requirement for cap recognition.

Adenoviruses appear to employ several mechanisms to disrupt cell protein synthesis to their own advantage. Firstly, they can control export of mRNAs from the nucleus. Virus-encoded proteins associate with a cellular RNA transport factor and sequester it in the region of viral replication and transcription. This has the effect of selectively facilitating viral transcript export to the detriment of cellular mRNAs. Secondly, small RNA transcripts known as virus associated (VAI) RNAs are produced in large quantities late in infection and these inhibit the interferon response activated kinase, PKR. Thus the PKR is unable to phosphorylate and inactivate the translation initiation factor eIF2α. As the VAI RNAs are associated with viral transcripts they may selectively protect the virion transcripts from eIF2α phosphorylation. Thirdly, late viral transcripts are able to avoid the inhibition of translation due to phosphorylation of the initiation factor, eIF4F. This is because of a unique property of the so-called tripartite leader sequence common to all late transcripts which allows the translation initiation complex to jump directly from the 5′ cap to the initiating AUG codon without having to scan the intervening sequence. Finally, a late viral protein is able to specifically activate translation of viral transcripts. Rotaviruses produce a protein that interacts with the initiation factor eIF4G to disrupt its interaction with poly(A)-binding protein. This leads to inhibition of translation of polyadenylated cellular transcripts and favoring the nonpolyadenylated viral transcripts.

Infection by a number of viruses leads to reduction in the levels of host mRNAs. In herpesviruses, for example, one of the virus particle-associated proteins that are introduced into the cell during infection seems to be or to activate a nonspecific ribonuclease. This degrades both host and viral mRNAs, but its activity seems to diminish during infection resulting in a selective accumulation of viral transcripts.

PROTEIN TRANSPORT

Viruses make use of the wide range of signalling and transport systems present in host cells to direct their proteins to appropriate compartments. For example, signal sequences are present at the N terminus of proteins destined for secretion into the endoplasmic reticulum, a compartment that is topologically outside the cell. These are relatively short hydrophobic amino acid sequences that associate with the secretory mechanisms and result in the extrusion of the nascent protein through specific pores in the endoplasmic reticulum (ER) membrane. As this occurs concomitantly with translation ribosomes and polysomes that are synthesizing secreted proteins are intimately associated with the ER membrane. The signal sequence is usually cleaved from the nascent polypeptide by proteases resident in the ER lumen. Proteins destined to become membrane proteins are prevented from being secreted completely by stop transfer sequences and remain anchored to the membrane by hydrophobic stretches of sequence and usually have a C-terminal cytoplasmic domain that may be involved in particle assembly or in signal transduction from interactions involving the extracellular domain. Having been inserted into the ER lumen, the proteins are usually glycosylated and can be transported to various cellular locations as dictated by further recognition signals, often located in the transmembrane domain or cytoplasmic tail. Viruses also use many other intracellular transport systems to distribute their proteins to defined destinations. For example, influenza virus ribonucleoprotein cores interact with cellular proteins to facilitate their transport to and through nuclear pores. Many viral proteins have nuclear location signals and others are able to reversibly shuttle between nucleus and cytoplasm to transport viral components between these compartments. Progeny poxvirus particles are able to stimulate the polymerization of actin and this enables them to be physically pushed through and out of the cell.

PROTEIN PROCESSING

Proteolytic cleavage

Proteolytic cleavages are involved in the replication strategies of many viruses. Practical evidence of their importance is furnished by the success of inhibitors of the virus protease in HIV therapy. Proteolytic cleavages can be broadly divided into two classes, those carried out by host cell proteases and those performed by virus encoded enzymes. The most common examples of the former are the normal modifications of secreted glycoproteins by signal peptidases which remove signal sequences in the ER lumen and signal peptide peptidases which can cleave within the transmembrane portion of the signal sequence. In addition, the surface proteins of many viruses are cleaved by cell surface proteases, such as furins, to prime them for subsequent conformational changes involved in the cell entry process, as discussed earlier. A good example is the HA protein of influenza virus which is synthesized as the precursor protein, HA0. This is activated to a cell fusion competent form by cleavage into HA1 and HA2. Mutations at this cleavage site can influence its susceptibility to cleavage, which in turn can have profound effects on the tissue tropism and pathogenicity of the virus.

Many viruses encode their own proteases which are used in the processing of precursor polyproteins. This is especially important for the single-strand positive-sense RNA viruses, such as the *Flaviviridae* and *Picornaviridae*

which translate their entire genome as a single polyprotein (Figure 4). This is processed by a cascade of proteolytic cleavages which function in *cis* or in *trans* to produce the final mature proteins. In the *Picornaviridae*, this strategy serves to increase the functional flexibility of a small genome as many of the intermediate proteins produced in the processing cascade have properties and functions that are distinct from those of the final mature products. In addition, the viral proteases are used to cleave specific cellular proteins, such as the translation initiation factor eIF4G, which results in the shut-off of host protein synthesis. In some cases, particularly with the nonenveloped viruses, virus-induced proteolysis also produces maturation cleavages involved in virion assembly. Proteolysis is also important for controlling the complex series of events in the assembly of herpesviruses. Core particles are initially assembled in the nucleus around scaffolding proteins. The scaffolding proteins are then cleaved by a virus protease and removed from the particles prior to packaging of the viral DNA.

Glycosylation

The great majority of secreted eukaryotic proteins, whether they are shed from the cell or remain tethered to cellular membranes by membrane insertion sequences, are post-translationally modified by the addition of carbohydrate residues. Glycosylation probably serves several functions: involvement in the folding process to produce the correct protein conformation, protection of the protein from extracellular enzymes, intercellular recognition, and, in the case of viral glycoproteins, to help mask the protein from immune recognition. Glycosylation of viral membrane proteins is carried by host-cell enzymes in accordance with the same biochemical rules as host proteins. There are two sorts of glycosylation, *N*-linked or *O*-linked of which the former is the dominant form. The recognition signal sequence Asn–X–Ser/Thr is essential for *N*-linked glycosylation, which occurs in the lumen of the ER. The initial step in *N*-linked glycosylation consists of the addition of a multibranched structure consisting of two residues of *N*-acetylglucosamine, nine of mannose, and three of glucose. The glucose residues report on the folding state of the protein, which is released from the chaperone, calnexin, when all have been removed. Further modifications of the carbohydrate chains are carried out in a cell-specific manner in the Golgi apparatus as the protein migrates through the secretory machinery.

Other post-translational modifications

A number of other modifications of viral proteins have been observed. One of the most important is phosphorylation which is used in many host cell and viral examples as a mechanism for inducing reversible conformational changes in proteins, so enabling them to act as molecular switches. Cascades of phosphorylation and dephosphorylation are the most widely used mechanisms for transducing messages from receptor interactions at cell surfaces to effector molecules in the nucleus. Many virus proteins are also modified by phosphorylation which probably alters their interactions with other proteins and/or nucleic acids, but in most cases their function is poorly understood.

A number of viral proteins are known to be modified by fatty acid acylation, the most common being N-terminal myristoylation. The 14 carbon myristic acid is added to the N-terminal amino acid (after removal of the initiation amino acid, *N*-acetyl methionine) of proteins starting with the sequence Gly–X–X–Ser/Thr. It is thought to be important for the interaction of proteins with membranes and may also be involved in 'molecular switching,' in conjunction with phosphorylation. For example, the small internal protein, VP4, of most picornaviruses is myristoylated and there is evidence that the protein interacts with cell membranes to create pores or channels when it is externalized during the infection process. The Nef protein of HIV is also myristoylated and this modification is probably involved in its ability to interact with intracellular membranes to dictate its intracellular localization. It is possible that conformational changes, perhaps induced by phosphorylation, may sequester the N-terminal region, including the myristate moiety, within the structure of the protein and so reversibly alter its distribution within the cell. Other modifications, such as sulfation, poly(ADP) ribosylation, and palmitoylation have been reported but their functions are not well understood. In some cases, proteins involved in viral replication are modified by the addition of nucleosides to enable them to function as primers to initiate nucleic acid synthesis. For example, the small genome linked protein, VPg, of picornaviruses is modified by the addition of one or two uridine residues on the side chain of a highly conserved Tyr residue, after which modification it can function to initiate replication of the viral RNA.

GENOME REPLICATION

DNA viruses

A problem inherent in cellular DNA replication is that of terminal loss. The priming and replication systems in normal cells lead to the loss of small amounts of sequence at each round of replication of the chromosomal DNA. This is overcome by the action of telomerase that adds back sequence to the termini so that there is no loss of important sequence. Viruses do not use this nonspecific addition system and have overcome

the problem of terminal loss in several interesting ways. One of the best studied viruses from a replication perspective is SV40 which overcomes the problem by having, in effect, no end. The genome is circular and during replication it produces daughter circles. Most of the enzymes involved in the replication are recruited from the host cell, but the process is initiated and controlled by the multifunctional viral protein, TAg. This binds to the origin of replication sequence as a hexameric complex and opens the complementary DNA strands. It has a helicase function which continues to enlarge the separated domain to allow access by the plethora of proteins involved in normal cell DNA replication. As all DNA is copied in the 3′ to 5′ direction, one strand is replicated discontinuously in a series of small steps (Figure 8). These are primed by short RNA sequences synthesized by DNA primase and extended as DNA sequence by Pol α. The RNA primers are excised by RNase H and the single-stranded region thus exposed is filled in by Pol α and joined to the preceding DNA segment by DNA ligase. The opposite strand is extended continuously by Pol δ from a single RNA primers sequence. Thus replication proceeds as two continuously moving forks, one moving in each direction. When they meet, two double-stranded circular DNA molecules have been replicated from one.

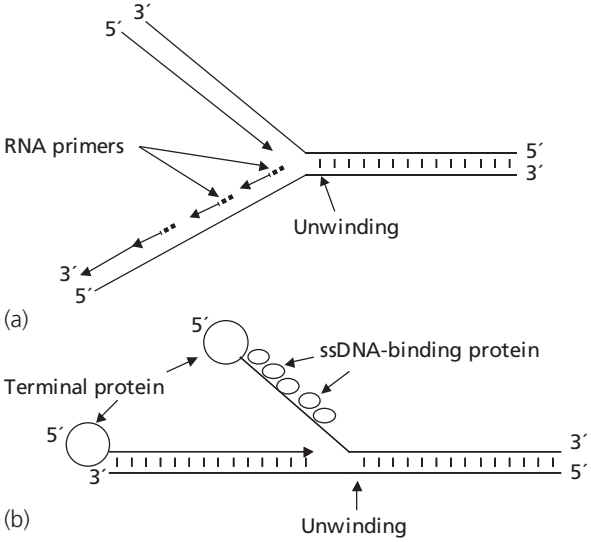

Figure 8 *Genome replication strategies of DNA viruses.* **(a)** *Replication of most double-stranded DNA viral genomes, SV40, for example, proceeds as a replicating fork with each of the parental strands being copied simultaneously. Since DNA polymerase is unidirectional, proceeding from the 3′ end of the template towards the 5′ end, the two parental strands are copied differently, one continuously, the other discontinuously. Discontinuous synthesis is primed by short RNA molecules 9–10 nt long which are subsequently removed when the nascent DNA fragments reach 100–200 nts. The resulting gaps are filled in with deoxyribonucleotides and the discontinuous fragments ligated together.* **(b)** *In the adenoviruses, a single nascent strand displaces one of the parental strands during synthesis. DNA synthesis is primed by terminal protein, which is modified by the addition of nucleotides complementary to the 3′ end of the viral sequence. The progeny molecule is encased in single-stranded DNA binding protein and this complex acts as template for synthesis of a complementary strand to recreate the double-stranded genome. Synthesis of the second strand is also primed by terminal protein.*

Another way of preserving ends is exemplified by the parvoviruses. These single-stranded DNA viruses have inverted repeats at their termini which, therefore, resemble self-priming molecules and are extended to form a hairpin structure. A sequence-specific cleavage occurs near the self complementary loop and the exposed 3′ end is extended to produce a complete double-stranded copy of the genome. Rearrangement of the palendromic end sequences exposes a free 3′ end which is copied back on itself to displace the partner strand as a new single-stranded viral DNA.

Some viruses, such as the adenoviruses, overcome the terminal loss problem by using a protein, to which nucleotides have been covalently attached, as a primer for DNA synthesis. The terminal protein of adenoviruses has a short chain of three nucleotides attached which complement a sequence near the 3′ end of the double-stranded viral DNA. In the presence of the viral polymerase and host factors the end of the DNA is melted and the terminal protein binds via its complementary nucleotides. The complex then jumps back by three nucleotides to bind to a repeat of the recognition sequence located at the extreme 3′ end and then proceeds to copy the entire DNA. Replication proceeds in a single direction, displacing one of the template strands as a single-stranded product (Figure 8). This is converted into a double-stranded molecule by the viral polymerase, again using terminal protein as a primer.

The complementary strands of poxvirus DNA are covalently linked so that the molecule is in effect an unbroken hairpin. The herpes virus replication products are continuous concatenated molecules and are cut into genome length units during the encapsidation process.

‘Reversiviruses’

Retroviruses and hepatitis B viruses alternate between DNA and RNA versions of their genomes at different stages in the replication cycle using reverse transcriptase. In both cases the replication strategies rely on the presence of terminal repeat sequences in the RNA versions of their genomes (Hu and Seeger 1997). Replication starts at a sequence near the 5′ end of the genome RNA. In the case of retroviruses the primer used to initiate replication is a host tRNA, which is extended by the viral reverse trancriptase as a DNA copy. In hepatitis B viruses an N-terminal domain of the polymerase protein acts as a protein primer, recognizing a stem loop structure in the RNA (Figure 9). In both cases the nascent DNA molecule is extended to the end of the template RNA at which stage it is transferred to a

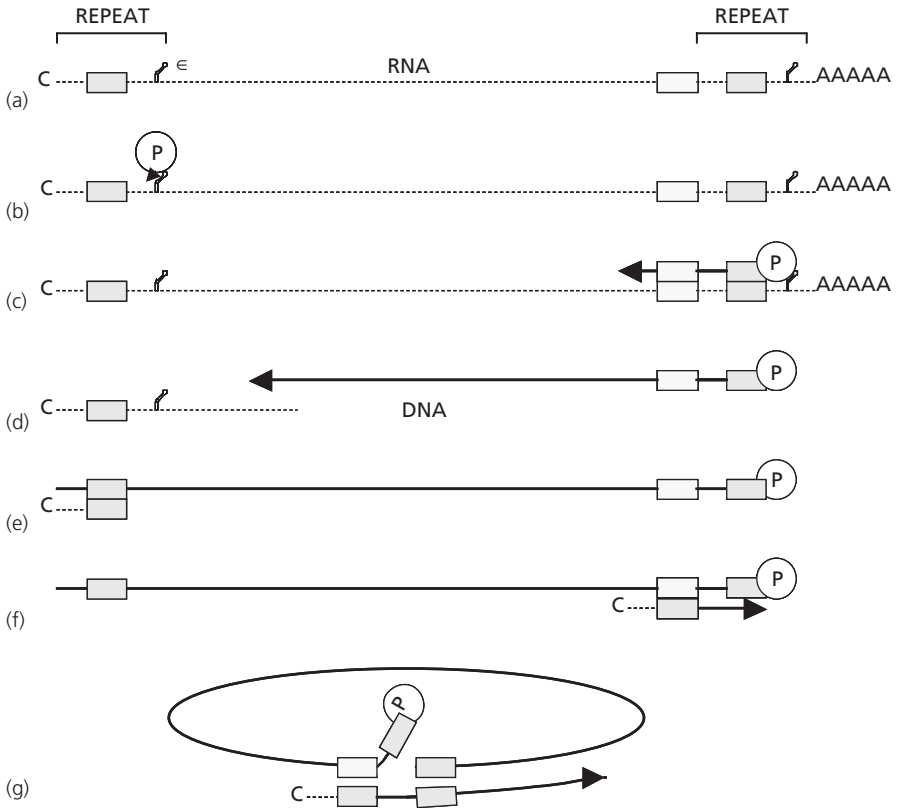

Figure 9 *Replication of the hepadnavirus genome. The genomes of hepadnaviruses (e.g. hepatitis B virus (HBV)) and retroviruses alternate between RNA and DNA forms, but at different stages in their life cycles. In both cases, reverse transcriptase copies RNA into a DNA strand and then functions as a DNA-dependent DNA polymerase to synthesize the complementary DNA strand. Repeated sequences at the ends of the molecules are essential for completion of the process.* **(a)** *The pregenomic RNA showing terminal repeat sequences (boxed) and the ϵ structure at which priming of DNA synthesis occurs.* **(b)** *The polymerase binds to the ϵ sequence and primes DNA synthesis via nucleotides linked to its terminal protein domain.* **(c, d)** *The replication complex with nascent DNA fragment is transferred to a complementary sequence at the 3′ end of the RNA and DNA synthesis proceeds towards the 5′ end of the template. The RNase H function of the polymerase protein digests the RNA template as synthesis proceeds.* **(e)** *A residual RNA fragment remains undigested and this is transferred to a complementary sequence towards the 5′ end of the cDNA to initiate synthesis of the second DNA strand* **(f)**. **(g)** *The molecule is then circularized through interactions of the complementary terminal regions and synthesis of the second strand continues. The replication of retroviral genomes is similar in principle, except that a host tRNA is used as the primer for initiation of DNA synthesis.*

repeat sequences at the 3′ end of the RNA from where it is extended to make a complete DNA copy of the genome. In both cases an RNase H activity is associated with the reverse trancriptase and this removes the RNA template. A small residual RNA sequence is used to prime synthesis of the second strand of DNA using the first strand as template. In the retroviruses, the DNA product is integrated into the host genome whereas the hepatitis B virus DNA remains as an episomal circular molecule in the nucleus. In both cases RNA transcripts, both mRNA and viral RNA are produced by host DNA-dependent RNA polymerase.

RNA viruses

HEPATITIS D VIRUS

Hepatitis D virus is unique amongst animal viruses and has a single-stranded circular RNA genome. It encodes a single viral protein which modifies host-cell polymerase to enable it to make transcripts from the viral genome. The transcript is synthesized as a continuous molecule which is pealed off from the circular template by a ‘rolling circle’ mechanism. An 83 nucleotide sequence within the viral RNA is highly structured and acts as an RNA enzyme or ribozyme (Shih and Been 2002). This is able to cut the RNA at a specific nucleotide to produce genome length segments of RNA and to ligate the ends to regenerate a circular molecule. The ribozyme functions on both the positive- and negative-sense RNAs.

POSITIVE-STRAND RNA VIRUSES

The genomes of the positive-strand RNA viruses must perform two apparently incompatible functions: to act as mRNA for viral protein translation and as templates for viral replication. As these functions start from opposite

ends of the RNA, there is the potential for conformational clashes for molecules performing both functions simultaneously. How this is prevented is only just beginning to be resolved and appears to involve crosstalk between the termini of the RNA by host and protein factors (Gamarnik and Andino 1998). Priming can involve a protein primer, as in the picornaviruses, or the polymerase can initiate synthesis de novo as in the case of hepatitis C virus. Picornavirus RNA replication is primed by the small protein, VPg, which is urydilated by the viral polymerase by a poorly understood mechanism which also involves a conserved stem–loop structure in the RNA, the *cis*-acting replication element (CRE). The primer-independent initiation seen in some viruses appears to require precise structural features of the polymerase to ensure that synthesis starts with the correct nucleotide. Progeny positive-strand RNA is typically produced in large excess ($\times 10$) over negative strand, but the mechanisms governing this imbalance are poorly understood.

NEGATIVE-STRAND RNA VIRUSES

In contrast to positive-strand viruses, the genomic RNA of negative-strand RNA viruses is always found as a ribonucleoprotein complex. This has to function as the template for the transcription of mRNAs and as template for genome replication. The switch from mRNA template to genome template function is determined by the levels of nucleoprotein available in the cell (Portela and Digard 2002). As this increases later in infection so the nascent transcripts are encapsidated and the polymerase functions in an antitermination mode, ignoring the sequence signals important for transcription of individual mRNAs. More recent evidence suggests that for VSV the P and L proteins are important, in addition to the nucleocapsid protein, N, and that different complexes are involved in transcription or replication.

DOUBLE-STRANDED RNA VIRUSES

The replication of the double-stranded RNA viruses occurs entirely within viral core particles. The infecting virus particle is stripped of its outer protein shells to reveal the core particle which contains multiple double-stranded RNA genome segments and the transcription machinery. This transcriptional machine is highly ordered and extrudes nascent positive-strand progeny RNA molecules through pores at the vertices of the icosahedral particle. These act as templates for both translation and for the production of new double-stranded viral genomes. The latter event occurs within newly assembled core particles which can then function to amplify the production of further positive-strand RNAs or to assemble into progeny virus particles. A fascinating and as yet unresolved feature of the double-stranded RNA viruses is that each core particle appears to assemble with a complete set of genome RNA segments. Part of the supporting evidence for this is that these viruses have very high infectivity to particle ratios, implying that all or most particles must contain a complete set of genome segments. How this selection process is controlled is not known.

RNA synthesis does not require a primer and the crystal structure of the polymerase of the double-stranded RNA phage, $\phi 6$, has demonstrated a novel mechanism for the initiation of replication. The structure of the active site pocket of the enzyme is so constructed that the 3′ end of the template strand abuts a structural 'wall' which holds it in place to pair with the first substrate molecules. As these are covalently linked the template strand progresses though the active site, effectively pushing the restraining wall from its path. Interestingly, studies of the crystal structure of the polymerase of hepatitis C virus, which also initiates RNA synthesis in a primer-independent fashion, suggest that a similar mechanism operates in that virus (van Dijk et al. 2004).

As a group, negative-strand RNA viruses include some of the most dreaded human viruses, such as Ebola virus, Lassa fever virus, Crimean-Congo hemorrhagic fever virus and rabies virus, as well as the causes of many common human infections such as influenza, measles, and mumps. Some negative-strand viruses infect domestic animals or plants, causing substantial disease and crop losses, and thus the overall impact of these viruses on human well-being is immense. Negative-strand viruses are united by the coding strategy of their genomes, though they display great variation in both biological and molecular characteristics. In this chapter, an overview of common features in replication is presented; more detailed reviews are provided by the subsequent virus-specific chapters.

CLASSIFICATION OF NEGATIVE-STRAND RNA VIRUSES

By convention, mRNA is termed the plus or positive strand as it contains protein coding information in the directly translatable form. Baltimore (1971) developed a classification scheme for viruses based on the relationship of viral genomic nucleic acid to viral mRNA (Figure 1). Hence a strand of genomic nucleic acid that is of equivalent polarity to mRNA is also called positive, and the complement of the positive strand is called negative. Thus viruses could be divided into a series of classes, of which class V comprises the negative-strand RNA viruses. Although this classification scheme is little used today, the concept of positive- and negative-strand RNA viruses remains. (Note that the terms 'strand' and 'sense,' as in negative strand or negative sense, can be and are used interchangeably).

Viral classification is now under the auspices of the International Committee on Taxonomy of Viruses, which publishes regularly updated reports on classification in both printed (7th Report; Van Regenmortel et al. 2000) and World Wide Web (www.ncbi.nlm.nih.gov/ICTVdb/index.htm) media. There are seven families of negative-strand RNA viruses and three orphan genera that are not yet incorporated into higher taxons (Table 1, p. 3). The families can be separated into two groups, those whose genomes comprise a single molecule of RNA (these four families make up the order *Mononegavirales*; see The Order Mononegavirales) and those that have segmented genomes. Six of the families contain viruses that cause disease in humans, ranging from respiratory tract disease, through encephalitis to hemorrhagic fever. *Bornavirus*, the sole member of the *Bornaviridae* family, has been implicated in neurological disease in horses, and may be linked to psychiatric disease in humans, though this remains controversial (Staeheli et al. 2000). In addition, some viruses in the families *Rhabdoviridae* and *Bunyaviridae* can infect plants. Viruses in the orphan genera *Ophiovirus* and *Tenuivirus* also infect plants and share some similarities with bunyaviruses (van Regenmortel et al.

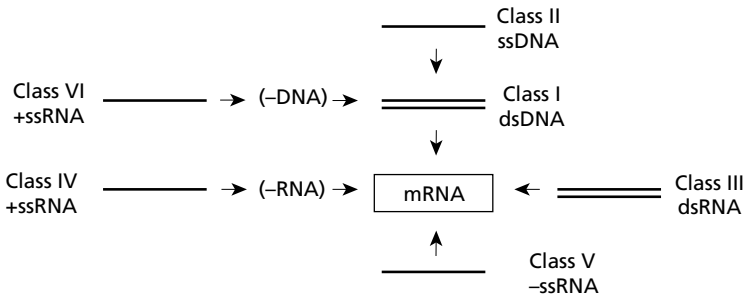

Figure 1 *The Baltimore Classification System. Viruses are classified according to the polarity and strategy of their genomes to produce mRNA. By convention, mRNA is designated the positive strand.*

2000). *Hepatitis delta virus* (HDV), the lone virus of the *Deltavirus* genus, is not usually mentioned when discussing negative-strand viruses, but is included in Table 1 for completeness. HDV has a 1.7 kb circular, negative-strand RNA genome that is heavily base-paired and more akin to a viroid genome. The genome encodes a single known product, the delta antigen, though this exists in two forms (large and small). HDV is obligatorily dependent on coinfection with *Hepatitis B virus* (HBV) for replication, and uses several HBV proteins to form its viral particle (Lai 1995; Gerin et al. 2002). HDV genome replication is quite distinct from that of the 'classical' negative-strand viruses; it occurs in the nucleus by a rolling-circle mechanism driven by cellular RNA polymerase II. The reader is referred to

Hepatitis delta virus for a detailed description.

OVERVIEW OF NEGATIVE-STRAND VIRUS REPLICATION

The implications for a virus possessing a negative-stranded genome are as follows: the genomic RNA itself cannot be translated into proteins directly, but must serve as the template from which positive-sense mRNA is copied. Since eukaryotic cells do not contain the appropriate enzyme to carry out this process – an RNA-dependent RNA polymerase (RdRp) – the infecting virus must encode and bring into the cell its own RdRp. As a consequence, and in contrast to positive-strand RNA viruses (Positive-strand RNA virus replication in vertebrate hosts), the isolated genomic RNA of a negative-strand RNA virus is not itself infectious.

All negative-strand RNA viruses share the property that the genomic RNA (and the antigenomic RNA that is synthesized during replication; Figure 2, p. 4) is encapsidated by the viral nucleoprotein (N or NP) and is associated with the viral polymerase components to form a ribonucleoprotein complex (RNP) or nucleocapsid. A feature of all negative-strand RNA viruses is that the RNP has helical symmetry. Both genomic and antigenomic RNAs are only found in RNPs and never as naked RNA, implying that encapsidation occurs concurrently during RNA synthesis. Furthermore, only RNP is the functional template for both transcription and replication.

In simplistic terms, all negative-strand RNA viruses replicate in a similar manner (Figure 2). After uncoating of the infecting virion, the genomic RNA (as RNP) is transcribed by the viral RdRp to produce viral mRNAs. These are translated to produce viral proteins, and once sufficient levels of protein have accumulated in the cell, the virus switches to replication mode. The same genomic RNP complex is the template for synthesis of an exact complementary copy of the genomic RNA – the antigenome – that is also encapsidated by the nucleoprotein. (Although this molecule is a positive-sense RNA, encapsidation by N protein prevents access to ribosomes and hence the antigenome cannot function as an mRNA). The antigenomic RNP is then the template for repeated synthesis of new genomic RNA molecules. These can be either packaged into progeny virus particles or act as new templates for further mRNA synthesis, termed secondary transcription. However, there are some key differences in the replication processes between nonsegmented and segmented genomes. In addition, the ambisense coding strategy (Bishop 1986; Nguyen and Haenni 2003) adopted by arenaviruses and some bunyaviruses shows further variation on the theme.

NONSEGMENTED NEGATIVE-STRAND RNA VIRUSES

Although the genomic RNA is packaged into helical RNP and the viruses are enveloped, the four families of nonsegmented negative-strand RNA viruses display a range of morphologies from spherical/pleomorphic (bornaviruses and paramyxoviruses), through bullet-shaped (rhabdoviruses) to filamentous (filoviruses), though variation is seen even within a family. Viruses in all four families share a core complement of genes that are arranged on the genome in a similar order (Strauss et al. 1996). The simplest genome structure is shown by rhabdoviruses (Figure 3, p. 4), such as vesicular stomatitis virus (VSV), which has just the core complement: N, P (phosphoprotein, a polymerase subunit), M (matrix), G (surface glycoprotein), and L (RdRp). More

Table 1 *Classification of negative-strand RNA viruses*

Family/subfamily/genus	Genome segments/ Size (kb)[a]	Site of replication	Host	Type virus[b] or virus associated with human disease
Order *Mononegavirales*				
Bornaviridae				
Borna disease virus	1/9	Nucleus	Vertebrate	Bornavirus: neuropsychiatric?
Filoviridae				
'Marburg-like viruses'	1/17	Cytoplasm	Vertebrate	Marburg virus: hemorrhagic fever
'Ebola-like viruses'	1/17	Cytoplasm	Vertebrate	Ebola virus: hemorrhagic fever
Paramyxoviridae				
Paramyxovirinae				
Respirovirus	1/15	Cytoplasm	Vertebrate	Human parainfluenza virus type 1: respiratory disease
Morbillivirus	1/16	Cytoplasm	Vertebrate	Measles virus: measles
Rubulavirus	1/15	Cytoplasm	Vertebrate	Mumps virus: mumps
Henipavirus	1/18	Cytoplasm	Vertebrate	Hendra virus: respiratory disease; Nipah virus: encephalitis
Avulavirus	1/15	Cytoplasm	Vertebrate	(Newcastle disease virus)
Pneumovirinae				
Pneumovirus	1/15	Cytoplasm	Vertebrate	Human respiratory syncytial virus: respiratory disease; croup
Metapneumovirus	1/13	Cytoplasm	Vertebrate	Human metapneumovirus: respiratory disease
Rhabdoviridae				
Vesiculovirus	1/11	Cytoplasm	Vertebrate	(Vesicular stomatitis Indiana virus)
Lyssavirus	1/12	Cytoplasm	Vertebrate	Rabies virus: rabies
Ephemerovirus	1/15	Cytoplasm	Vertebrate	(Bovine ephemeral fever virus)
Cytorhabdovirus	1/nc	Cytoplasm	Plant	(Lettuce necrotic yellows virus)
Nucleorhabdovirus	1/14	Cytoplasm	Plant	(Potato yellow dwarf virus)
Novirhabdovirus	1/11	Cytoplasm	Plant	(Infectious hematopoietic necrosis virus)
Bunyaviridae				
Orthobunyavirus	3/12	Cytoplasm	Invertebrate/ vertebrate	La Crosse virus: encephalitis; Oropouche virus: fever
Hantavirus	3/12	Cytoplasm	Vertebrate	Hantaan virus: hemorrhagic fever with renal syndrome; Sin Nombre virus: hantavirus pulmonary syndrome
Nairovirus	3/19	Cytoplasm	Invertebrate/ vertebrate	Crimean-Congo hemorrhagic fever virus: hemorrhagic fever
Phlebovirus	3/12	Cytoplasm	Invertebrate/ vertebrate	Rift Valley fever virus: hemorrhagic fever, retinitis
Tospovirus	3/18	Cytoplasm	Invertebrate/ plant	(Tomato spotted wilt virus)
Arenaviridae				
Arenavirus	2/11	Cytoplasm	Vertebrate	Lassa virus: hemorrhagic fever
Orthomyxoviridae				
Influenzavirus A	8/15	Nucleus	Vertebrate	Influenza A virus: influenza
Influenzavirus B	8/15	Nucleus	Vertebrate	Influenza B virus: influenza
Influenzavirus C	7/12	Nucleus	Vertebrate	Influenza C virus: respiratory disease
Thogotovirus	6/12	Nucleus	Invertebrate/ vertebrate	(Thogoto virus)
Isavirus	8/nc	Nucleus	Fish	(Infectious salmon anemia virus)
Orphan genera				
Ophiovirus	3/12	Cytoplasm	Plant	(Citrus psorosis virus)
Tenuivirus	4/5/18	Cytoplasm	Plant	(Rice stripe virus)
Deltavirus	1 (circular)/1.7	Nucleus	Vertebrate	Hepatitis delta virus: hepatitis

a) Approximate size; nc, not completed.
b) Nonhuman-type viruses are in parenthesis.

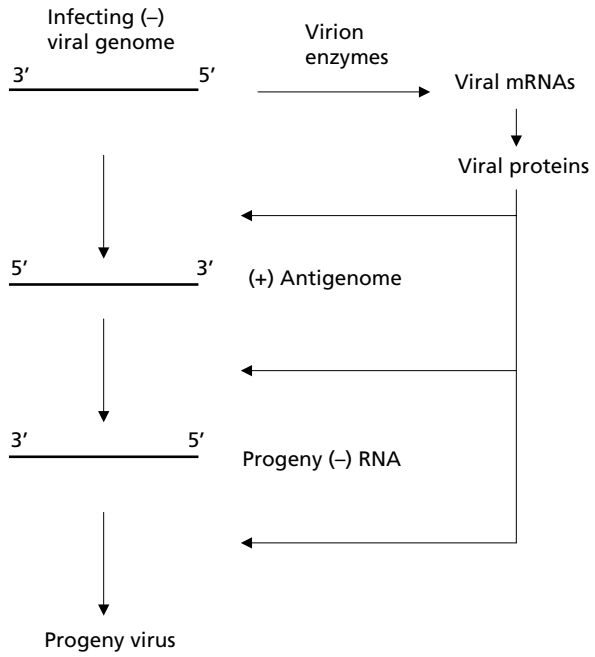

Figure 2 *Basic replication of negative-strand RNA viruses. The genome of the infecting virion is transcribed by the viral RdRp to produce viral mRNAs. The viral mRNAs are translated into viral proteins, that in turn are involved in replicating the infecting genome RNA via a complementary positive-strand RNA (the antigenome) and packaging into progeny virions.*

complex genomes such as paramyxoviruses encode other gene products such as additional glycoproteins and also nonstructural proteins. In all cases the genome is bounded by noncoding leader and trailer sequences, and each gene is flanked by transcriptional start and stop sequences. The internal genes are separated by intergenic sequences. Intergenic sequences range from just 2 nt in VSV to more than 60 nt in some paramyxoviruses. The gene stop sequences contain short tracts of U residues that template, via reiterative copying, the addition of a poly(A) tail at the 3′ end of the viral mRNA (Poon et al., 1999; Figure 3).

The generally accepted stop–start model of transcription (Banerjee et al. 1977; Emerson 1982), based largely on in vitro studies, is that viral RdRp begins RNA copying at a single promoter site at the 3′ end of the genome (Figure 3), and that termination of an upstream gene is required for subsequent transcription of the downstream gene. For VSV, a 47 nt leader RNA is synthesized and then released, and the RdRp initiates synthesis of the first mRNA, for N protein. The RdRp possesses capping activity so that the viral mRNAs have 5′ cap structures (m^7GpppG) similar to host cell mRNAs. After polyadenylation, the mRNA is released and the polymerase reinitiates after the intergenic sequence to synthesize the next mRNA. Transcription of the genome is thus sequential. During transcription, there is attenuation at each initiation step (the RdRp sometimes dissociates from the template and does not reinitiate), such that there is a gradient in the number of copies of each mRNA produced: N mRNA is most abundant and L mRNA the least abundant (Villareal et al. 1976; Iverson and Rose 1981). This is an important regulatory step for the virus in controlling the different amounts of each viral protein needed. For VSV, recombinant viruses have been created by reverse genetics (see later) in which the gene order has been rearranged (Wertz et al. 1998); although viable, such viruses grow less well than wild-type, confirming the importance of mRNA attenuation in viral replication.

Viral proteins are translated from the mRNAs and the amounts of these produced, particularly the N protein,

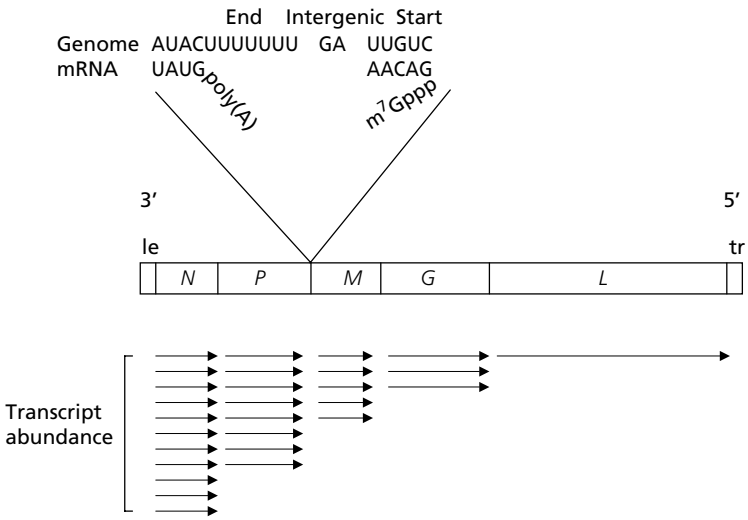

Figure 3 *Transcription of a nonsegmented negative strand RNA genome. The rhabdovirus VSV is used as an example. The five viral genes (*N, P, M, G, *and* L*) are flanked by leader (le) and trailer (tr) sequences. At each gene junction are found transcription termination and polyadenylation signals (end), an intergenic sequence (just 2 nt in the case of VSV) and a transcription initiation signal (start). There is attenuation of the polymerase at each junction, resulting in a gradient of transcript abundance from the 3′ to 5′ direction.*

are thought to signal the switch from transcription to replication. Sufficient N protein must be available to encapsidate the nascent antigenome RNA. Under these conditions the RdRp does not recognize the mRNA termination or polyadenylation signals but produces a full-length positive-strand RNA molecule that is cotranscriptionally encapsidated by N protein to make a positive-strand RNP. This in turn becomes the template for the synthesis of progeny genomic RNA, which again is cotranscriptionally encapsidated into RNP.

Recent in vivo studies (Whelan and Wertz 2002), however, provide evidence that the VSV polymerase can initiate transcription directly on the *N* gene start, and that prior transcription of leader RNA is not required. Thus the authors hypothesize that the regulation of transcription versus replication is through the polymerase binding to alternative sites on the genome: internally at the *N* gene for transcription and at the extreme 3′ end for replication. While this model has attractions, the factors responsible for which initiation site is used (possibly modification of the template or of the RdRp, or role of host-cell proteins, etc.) remain to be determined.

SEGMENTED GENOME NEGATIVE-STRAND RNA VIRUSES

A significant difference between orthomyxoviruses (e.g. influenza virus) and bunya- and arenaviruses is that the former transcribe and replicate their genomes in the nucleus. This presents an additional dimension to viral replication – transport of viral components in and out of the nucleus. After infection, the influenza virus RNPs must enter the nucleus, newly transcribed mRNAs exit the nucleus to be translated, viral proteins involved in RNP formation must travel back into the nucleus, and progeny negative-strand RNPs must transport out of the nucleus for virus assembly and release through the plasma membrane (Portela and Digard 2002). As orthomyxovirus mRNAs are produced in the nucleus, they can avail themselves of the cellular mRNA splicing machinery; for example, influenza A virus synthesizes differently spliced forms of mRNAs derived from RNA segments 7 and 8. These are translated into different proteins, thus increasing the coding capacity of these genome segments (Lamb and Krug 2001).

mRNA synthesis of all groups of segmented negative-strand RNA viruses is a primer-dependent process (Figure 4). The primers are derived from the capped 5′ ends of cellular mRNAs that are cleaved by an endonuclease activity contained within the PB2 protein of influenza virus or the L protein of bunya- and arenaviruses. The capped primers are incorporated into the viral mRNA, such that the viral mRNAs contain short (12–18 nt) nontemplated heterogenous sequences at their 5′ ends (Plotch et al. 1981). Thus these viruses do not need to encode capping functions unlike members of the *Mononegavirales*. This process, termed 'cap-snatching,' occurs in the nucleus for orthomyxoviruses and there-

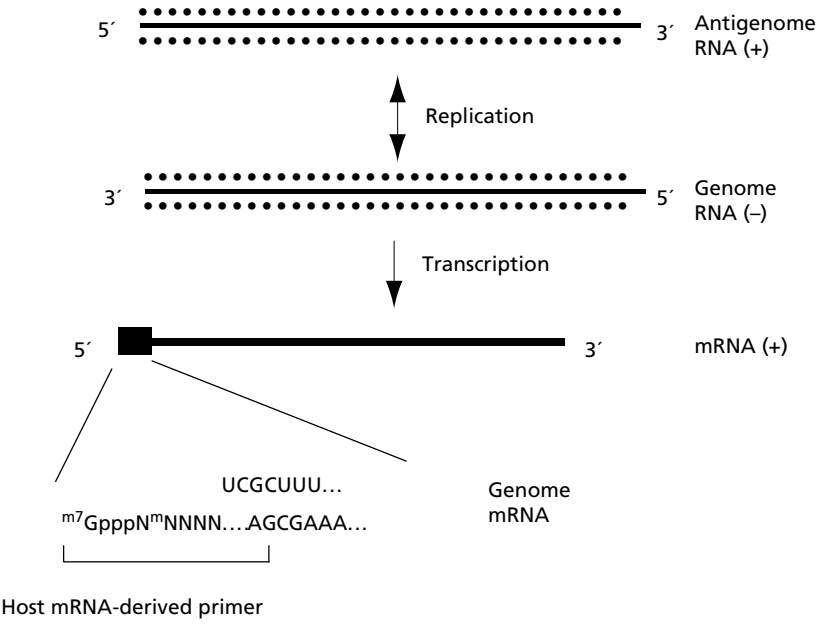

Figure 4 *Transcription and replication of a segmented negative-strand RNA virus. The genome and antigenome RNAs are shown encapsidated by nucleocapsid protein. Transcription to produce mRNA is a primer-dependent process where the capped, 5′ ends of host-cell mRNAs are cleaved by a viral endonuclease and the primers incorporated into the viral mRNA. The primers are usually 12–18 nt in length and heterogenous in sequence, though cleavage usually occurs at a base complementary to the 3′ end of the viral genomic RNA. The example shows the 5′ end of an influenza A virus mRNA. Viral mRNAs are truncated relative to the genome RNA, and are not encapsidated by nucleocapsid protein.*

fore needs ongoing host cell transcription; hence orthomyxovirus replication is inhibited by drugs, such as α-amanitin, which prevent host transcription. By contrast, bunya- and arenaviruses cap-snatch in the cytoplasm from previously synthesized host mRNAs and their replication is not inhibited by α-amanitin. Orthomyxovirus mRNAs are polyadenylated, signaled by a polyU stretch in the genomic RNA. Similar to the RdRp of nonsegmented viruses, the orthomyxovirus polymerase stutters on this sequence to add a poly(A) tail (Poon et al. 1999). By contrast, neither bunya- nor arenavirus mRNAs are polyadenylated (Nguyen and Haenni 2003).

The promoters for mRNA synthesis are located in the terminal untranslated regions of each genome segment. The 3′ and 5′ terminal sequences show a degree of complementarity that permits base-pairing between the ends, creating a panhandle, and accounts for the circular appearance of isolated nucleocapsids (Hsu et al. 1987; Pardigon et al. 1982). The relative strength of each promoter regulates the mRNA transcript abundance from each segment (Barr et al. 2003). Similar to the nonsegmented genome viruses, the concentration of viral N protein is thought to be involved in the switch to replication. RNA replication is a primer-independent event that results in production of full-length positive-strand RNAs (antigenomes) that are assembled into RNPs; these in turn serve as templates for synthesis of progeny genome RNA segments. Like the nonsegmented genome viruses, the newly synthesized genomic RNPs can be packaged into new virions or are involved in secondary transcription. In order to generate an infectious virus particle, one copy of each segment (at least) must be packaged, and there is debate over whether this is a random or specific event. Extraction of viral RNA from purified virions often reveals nonequimolar ratios of RNA, and it could be that virions contain more than just, for example, eight (influenza A virus) or three (bunyavirus) RNA segments. Recent work on influenza A virus has provided evidence for specific packaging signals that span the noncoding/coding region of some segments (Fujii et al. 2003).

AMBISENSE-CONTAINING VIRUSES

A variant of the classic negative-sense coding strategy is displayed by some genome segments of certain bunyaviruses and both segments of arenaviruses (Bishop, 1986; Nguyen and Haenni, 2003; Figure 5). Analysis of the genome RNA segments of these viruses reveals two open reading frames (ORF), one negative-sense and one positive-sense. These are separated by an intergenic region that typically shows secondary structure (often a stem-loop). The negative-sense ORF is translated from a subgenomic mRNA transcribed from the infecting genome in the usual manner, with transcription termination occurring at the intergenic structured RNA sequence.

The positive-sense ORF cannot be translated directly from the infecting genome since it is in an RNP form, but from a second subgenomic mRNA that is transcribed from the antigenomic RNA (Figure 5). Thus the negative-sense ORF is expressed early, whereas the positive-sense ORF is expressed later in infection, once genome replication has begun, giving the virus a degree of temporal regulation of gene expression. In all other regards, however, ambisense viruses replicate similarly to their strictly negative-sense counterparts.

GENETIC VARIATION, RECOMBINATION, AND REASSORTMENT

A particular feature of all RNA viruses is their genetic variability that is much higher than DNA genome viruses (Holmes 2003). This is because viral RdRp do not contain proofreading activity and thus when incorrect nucleotides are incorporated into the nascent RNA

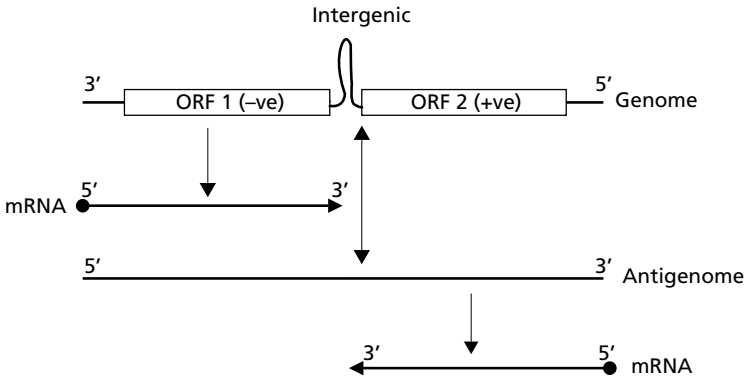

Figure 5 *Transcription and replication of an ambisense RNA. The genome RNA contains ORFs in both negative- and positive-sense orientations, separated by an intergenic sequence that usually shows secondary structure. Each ORF is translated from a subgenomic mRNA (transcribed in a primer-dependent manner), with the mRNA for ORF2 being transcribed from the full-length antigenome RNA. This means that the protein encoded by ORF2 is translated relatively late during the replication cycle, after the onset of genome replication itself.*

strand there is no means to correct them. The error frequency of RNA virus polymerases is in the range 10^{-3}–10^{-4}, resulting in rapid evolution of the virus. In fact, the resulting progeny genomes will each probably contain a nucleotide difference from the master or consensus sequence such that, rather than a homogeneous sequence, the virus consists of a population of related sequences known as a quasispecies. A consequence of this rapid evolution is that many progeny genomes will carry lethal mutations. The implications of this are to limit the size of RNA genomes – the bigger the genome the more chance of incorporating a lethal mutation. The positive-strand coronaviruses have the largest known RNA genomes, up to 32 kb (Coronaviruses, toroviruses, and arteriviruses), and the negative-strand viruses have genomes less than 20 kb. The ability of viruses to evolve and adapt to, for example, host immune pressure is clearly seen with influenza virus where the accumulation of point mutations year on year in the genes encoding the hemagglutinin and neuraminidase surface glycoproteins (antigenic drift) necessitates annual vaccination to maintain protection.

Genetic recombination – the breaking and joining of distinct nucleic acid molecules – has been regarded as a rare occurrence in negative-strand RNA viruses, but evidence is accumulating to suggest that it happens more frequently than previously thought, for instance in hantaviruses, arenaviruses, and paramyxoviruses such as mumps virus and Newcastle disease virus (Chare et al. 2003). However, at present, recombination is not seen as a major evolutionary force in these viruses.

By contrast, genome segment reassortment among the segmented viruses occurs frequently during the course of mixed infection. In this way progeny viruses may contain a genome comprising segments derived from each of the parents, though reasssortment is not entirely random. For as yet unknown reasons, certain genetic constellations are apparently not viable. Reassortment has been studied extensively in influenza viruses, where it is acknowledged as the route by which pandemic influenza virus strains arise – so-called antigenic shift (Reid and Taubenberger 2003). 'New' viruses emerge containing surface antigens not previously experienced by the human population (often the surface genes of an avian influenza virus) and thus the new strains cause havoc among the immunologically naïve population.

MAXIMIZING GENOME CODING POTENTIAL

Although all the viruses discussed in this chapter show the property of a negative-sense coding strategy, the viruses implement this in a number of variations to maximize the protein coding content of their genomes. The genomes encode protein highly efficiently – in general >90 percent of the genome encodes protein. As discussed above, influenza viruses encode different gene products from the same segment by splicing of the transcribed mRNAs. Orthobunyaviruses employ overlapping reading frames to encode two proteins on the S segment, both proteins being translated (unusually for a eukaryotic system) from the same mRNA (Bishop 1996). However, the extreme example of multiple protein expression from a single gene is shown by the paramyxovirus P gene, where up to six distinct proteins may be produced (Curran et al. 1998). Most paramyxoviruses exhibit RNA 'editing' during transcription of their P mRNAs, where nontemplated G residues (usually one, two or four Gs) are inserted, causing a frame-shift in the encoded mRNA. Thus different forms of mRNA are synthesized, encoding different proteins. Coupled with alternate initiation codon usage, including noncanonical AUG codons, a plethora of proteins can be produced from the single *P* gene. RNA editing also occurs in the glycoprotein mRNA of Ebola virus, producing both full-length and truncated glycoprotein products (Sanchez et al. 1996).

THE MODERN APPROACH TO STUDY RNA VIRUS REPLICATION: REVERSE GENETICS

One of the impediments to detailed analysis of RNA virus replication has been the nature of the genetic material itself; RNA is biochemically more labile than DNA, and techniques to produce specific nucleotide alterations directly in an RNA molecule are not available. In the field of RNA virology, 'reverse genetics' is usually described as the ability to recover (rescue) an infectious virus from cloned complementary DNA. Thus the viral genome can be manipulated at the DNA level using the full gamut of recombinant DNA protocols, and then virus recovered containing defined mutations. The phenotype of the mutant virus can then be related to the genotypic changes (hence **reverse** genetics). Reverse genetics of RNA viruses actually began in 1978 with the recovery of an RNA bacteriophage, Q**β**, from cloned cDNA (Taniguchi et al. 1978), and the first animal virus rescued from cDNA was the positive-strand poliovirus in 1981 (Racaniello and Baltimore 1981). However, progress on developing similar methodologies for negative-strand RNA viruses was more difficult, in part because of the requirement to produce a biologically active RNP form isolated components.

A system to manipulate individual genome segments of influenza A virus was reported by Luytjes et al. in 1989, but the first recovery of a negative-strand RNA virus entirely from cDNA was not achieved until 1994: perhaps surprisingly this was rabies virus by Schnell et al. (1994). Since then representatives of paramyxoviruses, filoviruses, bunyaviruses, and orthomyxoviruses have all been rescued entirely from cDNA (Conzelmann 1998; Neumann et al. 2002), and encouraging progress has

been made with bornaviruses and arenaviruses (Lee et al. 2000; Perez et al. 2003) to suggest that these will be rescued soon.

These achievements have led to unprecedented progress in understanding detailed aspects of viral replication, structure–function analyses of viral proteins, possibilities for engineering 'designer' vaccines, and in delineating viral–host interactions. These topics are dealt with in detail in the following chapters.

Positive-strand RNA virus replication in vertebrate hosts

JO ELLEN BRUNNER AND BERT L. SEMLER

Common characteristics across families	1	Conclusions	10
The intracellular replicative cycle	4	References	10

COMMON CHARACTERISTICS ACROSS FAMILIES

Classification and medical significance

This chapter is organized around the features of the intracellular replicative cycle shared by single-stranded, positive-strand RNA viruses that infect vertebrate hosts. Most of the discussion focuses on specific examples of viruses from the families *Picornaviridae*, *Caliciviridae*, *Flaviviridae*, *Togaviridae*, and *Coronaviridae*. Replication of single-stranded, positive-strand RNA plant viruses, a significant proportion of the viruses in this class, will not be covered here. The term positive-strand RNA refers to the taxonomic criterion proposed by Baltimore (Baltimore 1971) to classify viruses, namely, the relationship between the viral genome and the messenger RNA used for translation during the process of viral gene expression. Accordingly, a positive-strand RNA (class IV) virus has a genome that is identical to messenger RNA and competent for translation once released in the cytoplasm of the host cell. This scheme for virus classification does not necessarily take into account the more current genetic information which would form an additional basis for possible reassignments of viruses into superfamilies.

Poliovirus, the prototypic member of *Picornaviridae*, is arguably the most comprehensively studied mammalian single-stranded, positive-strand RNA virus. Much of the information and many of the mechanisms presented here come from the large body of knowledge relating to poliovirus. The majority of the early research concerning the biology and pathogenesis of the virus was motivated by the desire to diminish the human suffering caused by poliomyelitis, and subsequently led to the development of two effective vaccines. As a direct consequence of the widespread application of the Salk and Sabin vaccines during the last five decades, world health officials envision that poliomyelitis may be eradicated worldwide by the end of the year 2005. Ironically, the same scientific research which led to breakthroughs in the understanding of the molecular biology of poliovirus now creates the possibility that this virus could be reconstructed as an agent of bioterrorism in the post-eradication era (Cello et al. 2002).

Human immunodeficiency virus (HIV) is responsible for the current pandemic of acquired immunodeficiency syndrome (AIDS) and the associated climbing levels of worldwide morbidity and mortality. HIV and the other members of the *Retroviridae* are covered in subsequent chapters due to the fact that several aspects of their intracellular replication cycles are unique among single-stranded, positive-strand RNA viruses. Nonetheless, two other viruses of currently increasing medical importance globally, *West Nile virus* (WNV) (*Flaviviridae*) (Briese et al. 1999; Lanciotti et al. 1999; Jordan et al. 2000; Brinton 2002) and severe acute respiratory syndrome virus (SARS-CoV) (representing a new group of *Coronaviridae*) (Marra et al. 2003; Rota et al. 2003) are introduced.

Limited coding capacity of small genomes

The limited coding capacity of the relatively small genomes typical of most single-stranded, positive-strand

RNA viruses (approximately 4–30 kilobases) necessitates gene expression strategies aimed at generating multiple viral proteins or activities from apparent mono- or oligo-cistronic genomic RNAs (Figure 1). Viruses in the families *Picornaviridae* and *Flaviviridae* contain a single open reading frame (ORF) within their genomic RNAs which encodes a polyprotein that is processed into functional precursors and mature proteins (Agol et al. 1999; Brinton 2002; Leong et al. 2002). The viral structural proteins are encoded within the 5′ region of the genomic ORF, while the nonstructural proteins are encoded within the 3′ region. Human caliciviruses have small genomes that contain either three [Norwalk-like viruses (NLV)] or two [Sapporo-like viruses (SLV)] ORFs. NLVs express ORF1 as a polyprotein precursor that is cleaved by the viral 3C-like (picornaviruses) proteinase into the nonstructural proteins. ORF2 encodes the single major structural protein, and ORF3 encodes a small basic protein of unknown function (Clarke and Lambden 1997; Robinson et al. 2002). Other families within this class, *Togaviridae* and *Coronaviridae*, with their larger, more complex genomes, follow an expression strategy that involves discontinuous RNA synthesis. For togaviruses, production of subenomic positive-strand RNA(s) is templated from a full-length negative-strand intermediate RNA (Sawicki and Sawicki 1998a). A polyprotein processed into the nonstructural proteins is encoded by the 5′ end of the genomic RNA. A single subgenomic positive-strand RNA representing the 3′ end of the genome is translated into a polyprotein that is the precursor to the viral structural proteins.

For coronaviruses, the favored model of gene expression involves production of a set of subgenomic negative-strand RNAs, derived from discontinuous transcription of genomic RNA, which will serve as templates for transcription of subgenomic mRNAs (Makino et al. 1988; Sawicki and Sawicki 1998b). As with togaviruses, a polyprotein processed into the nonstructural proteins is encoded by the 5′ two-thirds of the genomic RNA. Coronaviruses generate a nested set of 3′ coterminal subgenomic positive-strand RNAs corresponding to the 3′ end of the genome. Each of these RNAs has at its 5′ end an approximately 70 nt long, capped leader sequence derived from the 5′ end of the genome (Holmes and Enjuanes 2003). The unique portion of the 5′ end of each mRNA is translated to synthesize an individual viral structural or nonstructural protein even though most of these mRNAs contain more than one ORF. Marra et al. identified nine potential ORFs within the SARS-CoV genome that could encode nonstructural proteins unique to this virus (Marra et al. 2003).

Another strategy which in effect amplifies the information encoded by the genome is the production of viral gene products that are multifunctional. The poliovirus precursor polypeptide, 3CD, is involved in protein

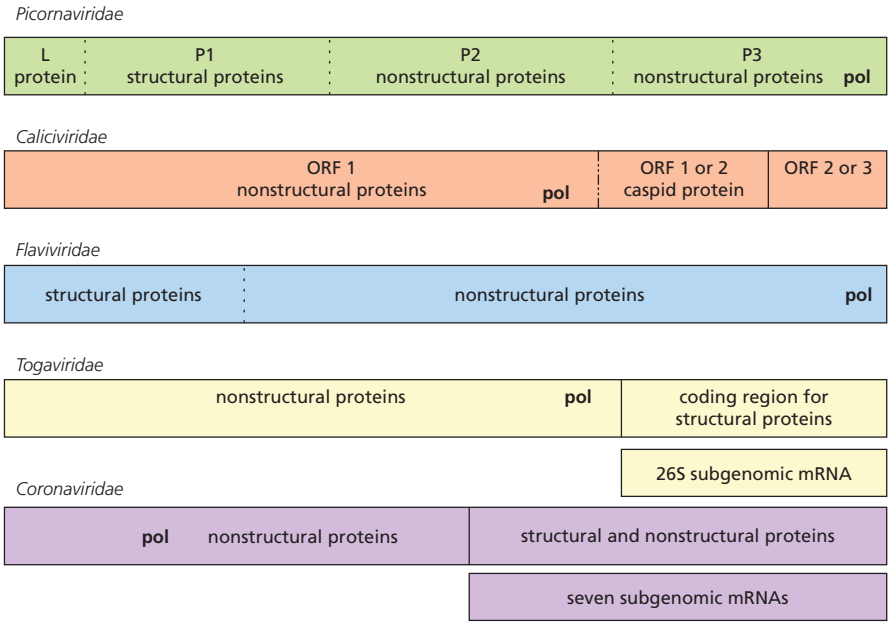

Figure 1 *Comparison of genome organization for five positive-strand RNA virus families. Picornaviruses and flaviviruses have a single ORF within their genomic RNAs. The structural proteins are encoded by the 5′ region of the genome and the nonstructural proteins are encoded by the 3′ region. Human caliciviruses have either two or three ORFs. The capsid protein is encoded by the 3′ terminus of ORF1 or ORF2. For togaviruses, a polyprotein processed into the nonstructural proteins is encoded by the 5′ region of the genomic RNA. A single subgenomic positive-strand RNA corresponding to the 3′ region of the genome is translated into a precursor to the viral structural proteins. For coronaviruses, a polyprotein processed into the nonstructural proteins is encoded by the 5′ two-thirds of the genomic RNA. Seven 3′ coterminal subgenomic positive-strand RNAs encode the structural proteins as well as some of the nonstructural proteins.*

processing as well as RNA replication, by way of replication complex formation with host and viral proteins at the 5′ and 3′ ends of the viral genome (Andino et al. 1990, 1993; Herold and Andino 2001). The NS5 protein of the *Flavivirus*, WNV, has methyltransferase and RNA polymerase activities (Brinton 2002). In fact, although the 11 kb genome of WNV is of intermediate length for a positive-strand RNA virus, most of the nonstructural proteins are multifunctional.

Investigators have long recognized that replication of many RNA viruses is cell-type specific, suggesting that there is a dependence on cell-specific factors (Lai 1998). RNA viruses are known to subvert host proteins that are normal components of cellular RNA processing or translation machineries for their own translation, replication, and packaging, another approach by which these viruses overcome the limited coding potential of their genomes (Table 1). The most frequently observed cellular proteins thought to be involved in viral RNA synthesis are the heterogeneous nuclear ribonucleoprotein (hnRNP) complex proteins. Several of these RNA-binding proteins, normally involved in assembly of the ribonucleosome and mRNA biogenesis, have been proposed to play a role in the life cycles of different viruses by interacting with viral RNAs in functional complexes (Lai 1998). hnRNP A1 binds to the 3′ untranslated region (UTR) and mediates potential 5′–3′ end crosstalk of the coronavirus mouse hepatitis virus (MHV) RNA.

Within the *Flavivirus* hepatitis C virus (HCV) genome, the 5′ UTR has been shown to interact with several cellular factors: the La autoantigen (Ali and Siddiqui 1997; Spangberg et al. 1999), polypyrimidine tract-binding protein (PTB) (Ali and Siddiqui 1995), hnRNP L (Hahm et al. 1998), eukaryotic initiation factor 3 (eIF3) (Sizova et al. 1998), and poly(rC) binding protein 1 (PCBP1) and poly(rC) binding protein 2 (PCBP2), also known as hnRNP E1 and hnRNP E2, respectively (Spangberg and Schwartz 1999). Human RNA-binding protein (HuR) and hnRNP C have been shown to bind to the 3′ ends of HCV RNAs of both polarities (Spangberg et al. 2000). PTB, also known as hnRNP I, interacts with the pyrimidine-rich region within the 3′ UTR of the HCV RNA genome (Gontarek et al. 1999). Eukaryotic elongation factor 1 alpha (EF-1α) interacts with the 3′ stem–loop structure of the genomic RNA of WNV (*Flavivirus*) and appears to play a functional role in replication (Blackwell and Brinton 1997).

Picornavirus investigators have determined that the cellular protein PCBP2 interacts with the major stem–loop structure in the internal ribosome entry site (IRES) of the 5′ noncoding region (NCR) of poliovirus positive-strand RNA and is essential for translation initiation (Blyn et al. 1996; Blyn et al. 1997). In addition, the binding of poly(rC) binding protein (PCBP) to the 5′ positive-strand cloverleaf structure in concert with the viral precursor 3CD is required for initiation of negative-strand RNA synthesis (Gamarnik and Andino 1997, 1998; Parsley et al. 1997; Walter et al. 2002).

Conservation of amino acid sequences, functional domains, and common replication strategies

Comparative analysis of amino acid sequences between positive-strand RNA viruses has revealed relationships between disparate groups of plant, animal, and bacterial viruses. Enzymes mediating the expression and replication of virus genomes contain arrays of conserved sequence motifs despite the potential for rapid evolution of RNA genomes (Koonin and Dolja 1993; Steinhauer and Holland 1987) Proteins that include such motifs are the RNA-dependent RNA polymerase (RdRp), a putative RNA helicase, a chymotrypsin-like proteinase and papain-like proteinase, and a methytransferase. Nonetheless, the RdRp is the only universally conserved protein of positive-strand RNA viruses. Evolutionary virologists are developing a concept of the RNA virus genome as a relatively stable foundation of housekeeping genes with a more flexible collection of genes coding for virion components and accessory proteins (Koonin and Dolja 1993). It is thought that all positive-strand RNA viruses and some related double-stranded RNA viruses could have evolved from a common ancestral virus that contained a gene for a RdRp, a chymo-

Table 1 *Examples of cellular proteins shown to interact with viral RNAs*

Virus	RNA	Cellular proteins
Poliovirus (*Picornaviridae*)	IRES – 5′ NCR of genome	PCBP2 (hnRNP E2), La, unr, PTB (hnRNP I)
	Cloverleaf – 5′ NCR	PCBP (hnRNP E)
	3′ NCR	Nucleolin
West Nile virus (*Flaviviridae*)	3′ Stem–loop of genome	EF-1α
Hepatitis C virus (*Flaviviridae*)	5′ UTR of genome	La, PTB, hnRNP L, eIF3, PCBP1 (hnRNP E1), PCBP2 (hnRNP E2)
	3′ End of + strand RNA	HuR, hnRNP C
	3′ End of − strand RNA	HuR, hnRNP C

Mouse hepatitis virus (*Coronaviridae*)	3′ UTR of genome	hnRNP A1

trypsin-related proteinase that also functioned as the capsid protein, and perhaps an RNA helicase.

Conservation of functional domains exists within the genomes of positive-strand RNA viruses in the form of *cis*-acting sequence motifs and RNA secondary structures necessary for translation, RNA synthesis, and packaging. The 5′ termini of these viruses typically contain such elements known to participate in binding of viral and host cell factors. Interaction of protein factors and RNA structures is necessary to selectively initiate viral-specific processes such as synthesis of negative-strand intermediate RNA. Binding of protein factors to internal sequence motifs can be a prerequisite to genomic RNA synthesis by implementing the release of single-stranded 3′ termini on negative-strand intermediate RNAs or by participating in a complex that initiates or increases the efficiency of genome replication.

Within the intracellular replicative cycle of most positive-strand RNA viruses, we see asymmetric production of excess genomic positive- over negative-strand RNA. Only a single, nascent negative-strand RNA is copied from a positive-strand RNA template at one time and the full-length duplexed RNA molecule that results from this transcription is referred to as the replicative form (RF). Although genomic positive-strand RNA synthesis may initiate on RF, eventually negative-strand RNA serves as the template for simultaneous synthesis of numerous new genomic RNAs by efficient reinitiation (Figure 2). This form of partially duplexed RNA is referred to as the replicative intermediate (RI). The fact that free negative-strand RNA is not recovered from the cytoplasm of the infected cell supports the replication models of RF and RI for picornaviruses, caliciviruses, flaviviruses, and togaviruses. The transition of the RdRp from competence for negative- to positive-strand RNA synthesis often involves the recruitment of additional host cell factors in temporal conjunction with availability of viral replication proteins.

In addition to demonstrating connection with respect to genomic organization, families within the class of positive-strand RNA viruses show similarity in the morphological types of virus particles assembled (Table 2). Viruses with cubic symmetry in the form of naked, icosahedral particles are seen in *Picornaviridae*, *Caliciviridae*, and *Astroviridae* and in the form of enveloped, spherical viruses with icosahedral nucleocapsids in *Togaviridae* and *Flaviviridae*. *Coronaviridae* includes viruses with more complex morphology, that is, spherical viruses with helical nucleocapsids and envelopes with long glycoprotein spikes.

THE INTRACELLULAR REPLICATIVE CYCLE

Initiation of the intracellular replicative cycle

The event that initiates the intracellular replicative cycle is the binding of a viral ligand to a receptor on the surface of a permissive host cell. These receptors, normally bound by cellular ligands, are utilized by virus particles for attachment at the plasma membrane. Host cell receptors thus far identified as the molecules used by positive-strand RNA viruses belong to several groups including the immunoglobulin-related proteins [poliovirus receptor (PVR); intracellular adhesion molecule

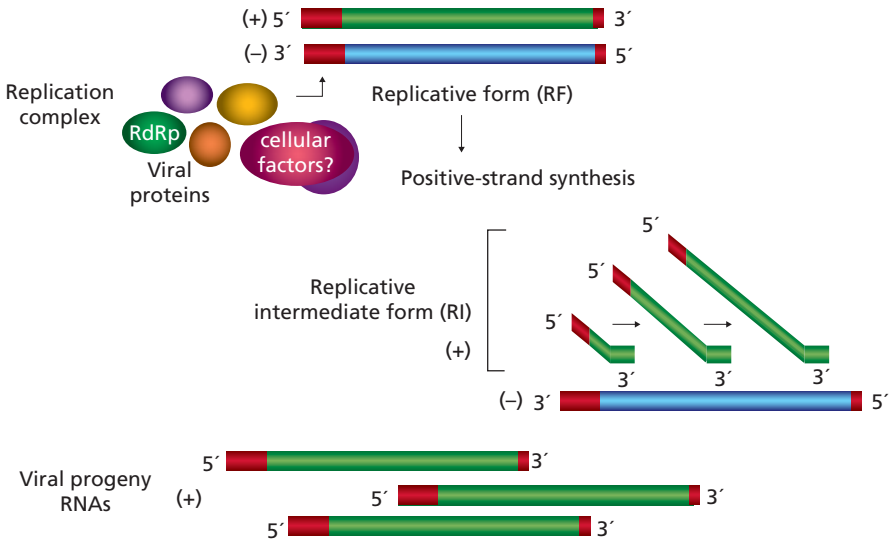

Figure 2 *Schematic representation of positive-strand RNA virus genomic RNA synthesis. A replication initiation complex, composed of the RNA-dependent RNA polymerase (RdRp), other viral proteins, and cellular proteins forms on the 3′ end of the negative-strand intermediate RNA or on the duplex RF. Multiples initiations on a single template produce an excess of positive-strand over negative-strand RNAs.*

Table 2 *Comparison of positive-strand RNA virus features by family*

Family	Enveloped	Polyprotein	Subgenomic mRNAs
Picornaviridae	No	Yes	No
Caliciviridae	No	Yes	No
Flaviviridae	Yes	Yes	No
Togaviridae	Yes	Yes	Yes
Coronaviridae	Yes	Yes	Yes

(ICAM)-1 – picornaviruses; mouse hepatitis virus receptor (MHVR)/biliary glycoprotein 1 (Bgp1) – coronaviruses], low density lipoprotein-related (LDLR) receptors (LDLR/α2MR/LPR – picornaviruses), integrins (αvβ3 – picornaviruses), receptors involved in complement pathways (CD55 – picornaviruses), as well as miscellaneous other receptors including aminopeptidase-N (coronaviruses), laminin receptor (togaviruses), and glycosaminoglycans (flaviviruses) (Young 2001). Viruses that are transmitted between insect and vertebrate hosts during their natural life cycle, such as some of the flaviviruses, are thought to use highly conserved cell receptor proteins (Brinton 2002). It is thought that alphaviruses and flaviviruses may use various receptor/coreceptor combinations to give the diverse host range (birds, mammals, mosquitos) and tropisms seen in vivo.

Viral ligands differ for each family, primarily based on either the presence or absence of an envelope with embedded glycoproteins. Naked viruses, such as members of the *Picornaviridae*, have a groove, or canyon surrounding each fivefold axis of symmetry in the capsid. These canyons have been shown to be the site of interaction with host cell receptors (Belnap et al., 2000b; He et al. 2000; Xing et al. 2000). Flaviviruses attach to host cells through an interaction between various receptors and the major viral surface protein, the E protein. Within the *Togaviridae*, the alphavirus envelope glycoproteins, E1 and E2, mediate binding of virus particles to host cell receptors. With coronaviruses, although the S protein is likely the main determinant of viral tropism due to specific cell surface glycoprotein binding, members containing the HE glycoprotein may bind to the common surface moiety, 9-*O*-acetylated neuraminic acid (Schultze and Herrler 1992).

Our understanding of the actual process whereby the virus particle or genomic RNA enters the cell has increased significantly in recent years. Virus particles such as poliovirus are thought to undergo conformational changes in the capsid proteins as the result of receptor binding. These changes expose hydrophobic domains on two of the capsid proteins which subsequently interact with the plasma membrane or endocytotic vesicle membrane, forming a pore through which the genomic RNA may be extruded and relocated into the cytoplasm of the cell (Hogle 2002). The movements of the capsid proteins that occur during this process have been compared with the movements of tectonic plates in the Earth (Belnap et al. 2000a). Human rhinovirus (HRV), a picornavirus, togaviruses (Smit et al. 1999), flaviviruses (Brinton 2002), and coronaviruses (Hansen et al. 1998) are thought to gain entry into the cytoplasm of host cells via the process of receptor-mediated endocytosis. Briefly, receptor-bound particles accumulate in coated pits on the cell surface, which are then endocytosed to form coated vesicles. These vesicles are subsequently uncoated to form acidified endosomes, which creates the environment that triggers low pH-mediated fusion of the viral capsid/envelope with the endosomal vesicle membrane and releases the nucleocapsid into the cytoplasm (DeTulleo and Kirchhausen 1998).

Translation of viral-specific RNAs and processing of polyproteins

Viral gene expression for positive-strand RNA viruses begins with translation of genomic (messenger) RNA in the cytoplasm. The structure of viral messenger RNAs differs somewhat between families with respect to modifications of the termini and presence or absence of an IRES (Table 3). Picornavirus genomes are uncapped, have a viral protein VP_g(3B), linked to the 5′ end, have either a type I or type II IRES in the 5′ NCR, and are polyadenylated at the 3′ terminus. Caliciviruses also have a VPg, linked to the 5′ end of their 3′ polyadenylated genomes. Togavirus and coronavirus genomes and subgenomic positive-strand RNAs are terminated with a 7-methylguanosine cap at their 5′ end and polyadenylated at the 3′ end. In flaviviruses, two different types of genomic RNAs exist. Viruses in the genus *Flavivirus* are capped with a 7-methylguanosine at the 5′ end but do not contain a 3′ polyadenylate (poly(A)) tract, while hepacivirus and pestivirus genomes are uncapped at the 5′ end, have an IRES in the 5′ NCR, and are not polyadenylated at the 3′ end. *Flaviviridae* is the only family of positive-strand RNA viruses, with members that infect mammalian hosts, that do not have a poly(A) tail at the 3′ end of the genome.

Since most cellular mRNAs are capped at the 5′ end, there are mechanisms which specifically select for translation of viral messages that are capped. In some cases, host-cell factors are involved in the favored recognition of viral mRNAs by the host translational machinery. Each coronavirus subgenomic RNA contains a 5′ leader sequence that enhances translation in lysates from virus-infected cells, suggesting that virus-specific mRNAs may be preferentially translated in the context of decreased host translation, brought about by competition for active ribosomes and degradation of host mRNAs in the infected cell (Tahara et al. 1994).

Although all but the smallest coronavirus mRNAs contain multiple ORFs, only the 5′-most ORF of each

Table 3 *Structure of positive-strand viral (genomic) mRNAs*

Family	5′-Linked protein or cap	IRES	3′-Poly(A)
Picornaviridae	VPg	Yes	Yes
Caliciviridae	VPg	?	Yes
Flaviviridae			
Flavi-	7-Methylguanosine cap	No	No
Hepaci-, Pesti-	Uncapped	Yes	No
Togaviridae	7-Methylguanosine cap	No	Yes
Coronaviridae	7-Methylguanosine cap	Yes (some downstream ORFs)	Yes

mRNA is generally translated by a cap-dependent ribosomal scanning mechanism. However, in several coronavirus mRNAs, the second or third ORF is preceded by an IRES and is efficiently translated by allowing ribosomes to bypass the upstream ORF and bind internally to the IRES.

Initiation of translation by cap-independent mechanisms involves some of the cellular proteins that function in cap-dependent translation. In cells infected by some picornaviruses, eIF4G is cleaved by a viral proteinase. The C-terminal fragment created by this cleavage, which contains binding sites for eIF3 and eIF4A, stimulates IRES-mediated translation of poliovirus RNA (Buckley and Ehrenfeld 1987). Several cellular proteins that bind to the picornavirus IRES have been identified. These include PTB (Hellen et al. 1993), PCBP2 (Blyn et al. 1996), the La autoantigen (Meerovitch et al. 1993), and unr (Hunt et al. 1999). It is thought that these cellular proteins may act as RNA chaperones, maintaining the IRES in a structure that allows direct binding to the translation machinery. Several cellular proteins, including PTB (Ali and Siddiqui 1995), the La autoantigen (Ali and Siddiqui 1997), and hnRNP L (Hahm et al. 1998), have been shown to interact with the 5′ NCR of HCV and function in the process of internal initiation of translation.

Polyprotein processing is required for the generation of functional polypeptides utilized by positive-strand RNA viruses. It is also a means by which they amplify the coding capacity of their relatively small genomes. For picornaviruses, almost all of the proteins necessary for a complete intracellular replicative cycle are found within the single long ORF of the genome in the form of intermediates and mature protein products. The full-length polyprotein product encoded by the ORF is never seen since viral-encoded proteinases begin cleavage cotranslationally. The initial processing events of the picornavirus polyprotein differ among the genera with respect to site and proteinase. Primary cleavage of the enterovirus and rhinovirus nascent polyprotein occurs at the P1/P2 junction and is mediated *in cis* by the viral-encoded 2A proteinase (Toyoda et al. 1986). For aphthoviruses, the primary cleavage at the L/P1 junction is thought to occur by enzymatic activity of L *in cis*, while for cardioviruses, the L protein is cleaved from the P1 region by the 3C proteinase. The 2A proteins of these two genera are not proteinases, but cause their own release at the junction with 2B by an unknown mechanism that appears to be a novel form of peptide bond scission (Palmenberg et al. 1992). In hepatoviruses and parechoviruses, 3C carries out the primary cleavage at the 2A/2B junction (Schultheiss et al. 1994; Stanway and Hyypia 1999). Viral proteinases L, 2A, and 3C (3CD) are active in the nascent picornavirus polypeptide and are involved in their own release by self-cleavage. All subsequent polypeptide cleavages occur *in trans*. For poliovirus, HRV, and coxsackie virus, the precursor, 3CD, is responsible for further processing of P1 following the initial cleavage (Ypma-Wong et al. 1988). The 3D portion of 3CD may be required for recognition of structural motifs in the folded P1 precursor allowing efficient processing by the 3C part of the enzyme (Parsley et al. 1999; Cornell and Semler 2002). The existence of multiple activities in a single proteinase provides another example of maximization of coding capacity of a small RNA genome.

The single large ORF of the flavivirus genome is translated as a polyprotein that is both co- and post-translationally processed by cellular proteases and viral-encoded proteinases. For HCV, the initial processing event of the polyprotein at the NS2/3 junction is mediated by the autoprotease, NS2-3. The NS3 serine protease, with the help of the NS4A cofactor, performs the other cleavages in the nonstructural region of the polyprotein. Cleavages within the structural region of the polyprotein are thought to be effected by the cellular resident endoplasmic reticulum (ER) signal peptidases (Houghton et al. 1994; Reed and Rice 2000).

The togavirus genomic RNA serves as the messenger RNA for translation of the polyprotein that is cleaved by a virally encoded protease (Hardy and Strauss 1989) to form the nonstructural polypeptides. Translation of the polyprotein is initiated at a single AUG near the 5′ end of the genome and proceeds continuously until encountering three termination codons located just downstream of the start of the sequences corresponding to the subgenomic RNA. Several of the alphavirus genomes have an opal stop codon upstream of the nsP4 coding region that is sometimes suppressed to allow read-through and inclusion of nsP4 in the polyprotein.

The final products of translation of the subgenomic mRNA are the capsid protein, released cotranslationally by autoproteolysis, two transmembrane glycoproteins, and a small membrane-embedded protein (Strauss and Strauss 1994) (Figure 3).

For MHV, a coronavirus, the structural proteins are each encoded by a separate subgenomic mRNA. However, two polyproteins translated from the replicase gene (gene 1) are processed by the viral-encoded proteinases, papain-like cysteine proteases (PLP1 and PLP2) and chymotrypsin-picornavirus 3C-like protease (3CLp), into at least 15 nonstructural protein products, including the presumed RNA helicase and the RdRp (Denison et al. 1999).

Alteration of the intracellular environment by viral gene products

Positive-strand RNA virus genomes encode nonstructural proteins that induce biochemical and structural changes in the host cell following infection (Figure 4). These viral proteins are thus indirectly involved in the process of RNA synthesis since they give rise to modifications in the environment where synthesis occurs. Down-regulation of cellular protein synthesis is one such common consequence of infection by nearly all members of the *Picornaviridae*. Cleavage of eIF4GI, eIF4GII, and poly(A) binding protein (PABP) by picornavirus 2A and/or 3C proteinases results in cessation of host translation due to destruction of the eIF4F complex and end-to-end communication in cellular mRNAs (Bushell and Sarnow 2002). For example, the synthesis of poliovirus proteins is not affected since the viral mRNA is translated by internal ribosome binding to the IRES, a mechanism that does not require an intact eIF4F complex. Since optimal function of the poliovirus IRES does require the C-terminal cleavage fragment of eIF4G, the modification of this cellular factor by 2A assists viral replication by inhibiting cellular translation and stimulating IRES-dependent translation. Cleavage of eIF4G in cells infected with foot-and-mouth disease virus (FMDV) is mediated by the viral L protein. Infection of cells with encephalomyocarditis virus and some of the other picornaviruses causes inhibition of cap-dependent translation as well, not by proteolytic cleavage of translation factors but by alteration of the phosphorylation state of two other cellular proteins, 4E-BP1 and 4E-BP2. Dephosphorylation of 4E-BP1, which allows it to bind to eIF4E and thus prevent formation of eIF4F and recognition of capped mRNAs, inhibits translation of cellular messages but does not affect translation of viral mRNA.

Intuitively, in strict consideration of the machinery of RNA synthesis, competition between virus and host may seem minimized by the fact that positive-strand RNA viruses code for their own RdRp. However, down-regulation of cellular transcription mediated by viral gene products would favor the synthesis of viral RNA by increasing the pool of free nucleotides available for the

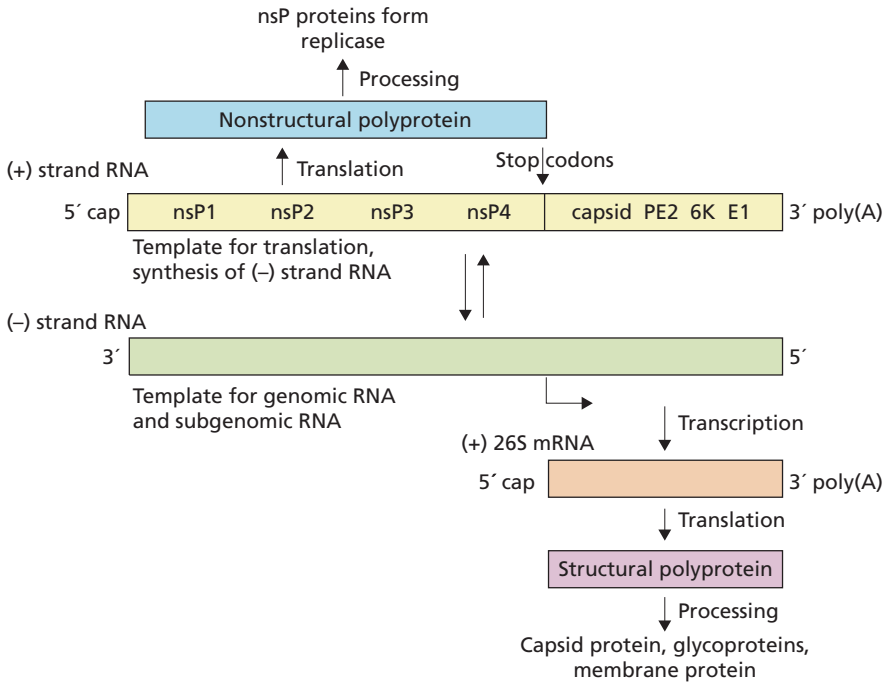

Figure 3 *Transcription and replication of alphavirus RNAs including translation and processing of polyprotein precursors. Positive-strand genomic RNA is the template for a full-length negative-strand intermediate RNA. The 5′ two-thirds of the genomic RNA encodes a polyprotein processed into the nonstructural proteins. The negative-strand RNA is the template for production of more genomic RNAs as well as the template for production of the 26S subgenomic mRNA that encodes a polyprotein processed into capsid protein, envelope glycoproteins, and membrane protein.*

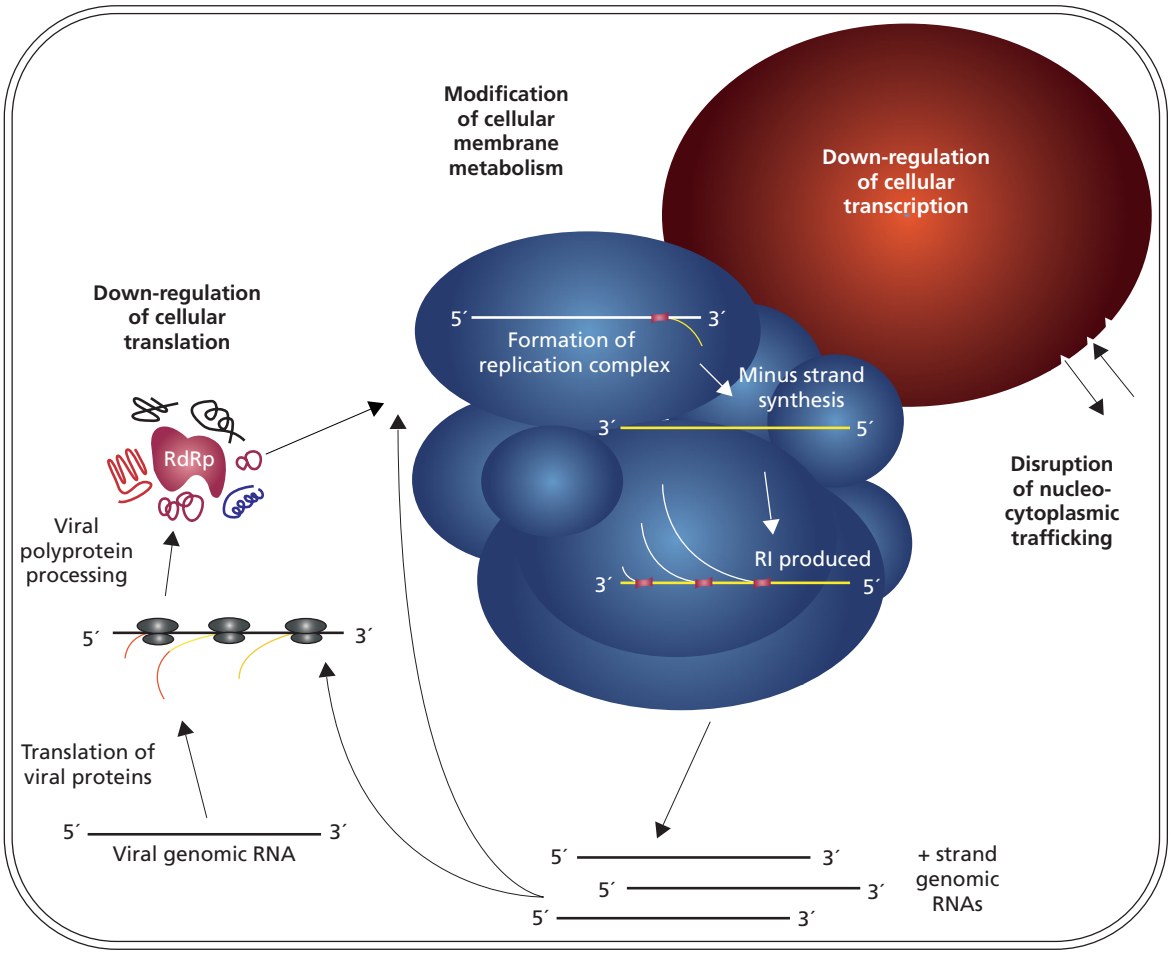

Figure 4 *Biochemical and structural changes in the host cell following infection by positive-strand RNA viruses. Down-regulation of cellular protein synthesis favors translation of viral mRNAs. Cellular transcription is often down-regulated, thereby increasing the pool of free nucleotides available for viral RNA synthesis. Excessive proliferation of intracellular membranes provides a matrix for viral RNA synthesis. Disruption of nucleocytoplasmic transport may result in an abundant pool of nuclear proteins in the cytoplasm that may assist with viral protein synthesis, RNA synthesis, assembly, or packaging. Red oval represents the nucleus; blue ovals represent cytoplasmic membranous vesicles.*

viral polymerase. Interestingly, at an intermediate to late time in the course of infection by most picornaviruses, there is a rapid inhibition of host cell RNA synthesis catalyzed by all three classes of DNA-dependent RNA polymerases. Since pol I, pol II, and pol III isolated from such cells are active, the inhibitory mechanism is thought to involve accessory transcription proteins. In fact, cleavage of TATA-binding protein (TBP) and other transcription factors, by poliovirus proteinase 3C and proteinase 2A, has been mechanistically associated with this transcription inhibition (Dasgupta et al. 2002).

During the intracellular replication cycle of positive-strand RNA viruses, modifications of cellular membrane metabolism and function commonly occur. For example, during flavivirus infection, there is extensive reorganization and proliferation of cytoplasmic, perinuclear endoplasmic reticular membranes (Brinton 2002). In picornavirus infection, there is an accumulation of small membranous vesicles thought to be caused by the inhibition of membrane vesicle transport from the endoplasmic reticulum to the cell surface. For poliovirus, viral proteins 2B, 3A, 2BC, and 2C are believed to be involved in this process (Cho et al. 1994; Doedens and Kirkegaard 1995). Such modifications of the cytoplasmic environment favor viral replication since the abundant, localized membranes not only provide a subcellular compartment which concentrates cellular and viral proteins but also serve as a matrix upon which viral RNA replication complexes can form.

Even though the positive-strand RNA viruses typically complete their replicative cycle strictly in the cytoplasm, there can be a disruption of nucleocytoplasmic trafficking as the result of viral infection (Gustin and Sarnow 2001, 2002). Alteration in nuclear import, export or both can result in an increase in the levels of nuclear proteins in the cytoplasm available for use in viral translation, replication, and/or packaging. In addition, disruption of signaling to the nucleus can attenuate the antiviral response by preventing transcription of the relevant cellular messages.

Genome replication

The process of RNA-dependent RNA synthesis is foreign to most eukaryotic cells, in which RNA synthesis normally occurs from a DNA template. Eukaryotic DNA-dependent RNA polymerases are formed by multiple subunits. Thus, although the RdRp elongation activity must be encoded by the viral genome, typically there is a dependence on cellular proteins to complete the replicase activity or provide specific selection of the viral template RNA. Cellular factors may serve as part of the RdRp holoenzyme by binding directly to the core enzyme, or they may direct the RdRp to the RNA template by binding directly to the template, or they may carry out both functions by forming a bridge between the RdRp and the RNA template (Lai 1998).

The first structure of an RdRp solved was that of poliovirus $3D^{pol}$ and it was found to have the same overall configuration as that of the other three types of polymerases, that is, DNA-dependent DNA polymerases, DNA-dependent RNA polymerases, and RNA-dependent DNA polymerases (reverse transcriptases) (Hansen et al. 1997). The native three-dimensional shape of all these polymerases is that of a cupped right hand, with domains corresponding to the thumb, palm, and fingers. The palm domain contains the active site of the enzyme. RdRps may not only be template dependent, but also primer-dependent enzymes as is the case for picornaviruses. The RdRp of poliovirus, $3D^{pol}$, copies the viral RNA in the presence of the uridylylated VPg (3B) protein primer.

The first step in RNA synthesis of positive-strand RNA viruses is synthesis of the complementary intermediate negative-strand RNA. With respect to a single strand of viral genomic RNA, it is generally assumed that viral translation is terminated prior to the initiation of negative-strand synthesis, since the ribosomes and RdRp would be unable to travel along the same molecule in opposite directions without colliding. In general, at the beginning of the replication cycle, nascent genomic RNAs may alternate between replication and translation until a sufficient pool of nonstructural proteins has accumulated.

Negative-strand RNA synthesis is presumed to be initiated at the 3′ end of the positive-strand RNA and requires proteins of both viral and cellular origin as well as *cis*-acting structural and sequence determinants in the genomic RNA. Since some viral RdRp do not bind directly to *cis*-acting regulatory elements on the viral RNA, initiation of RNA synthesis may depend upon interactions with cellular proteins or viral proteins that bind directly to the viral RNA. It is hypothesized that RNA viruses may assemble RNA transcription or replication complexes which bring noncontiguous regions of viral RNA together, similar to the interaction between enhancer and promoter elements in DNA-dependent RNA synthesis. One end of the viral RNA could function as an enhancer while the other end could serve as a promoter (Lai 1998).

Long-range interactions between the 5′ and 3′ ends of the viral genome mediated through protein–protein contacts have been studied in the context of initiation of negative-strand and/or positive-strand RNA synthesis. For poliovirus, it has been shown that PABP interacts with the cellular protein, PCBP2, and the viral polymerase precursor, 3CD (Herold and Andino 2001). These long-range interactions could bring the two termini of the viral genomic RNA together if PABP were bound to the 3′ poly(A) tail. For HCV, studies indicate that there may be 5′ to 3′ crosstalk between the termini of the RNA of both polarities which may be important for RNA transcription and replication (Huang and Lai 2001).

For single-stranded, positive-strand RNA viruses, RNA synthesis is asymmetric. Genomic RNA synthesis is more efficient than negative-strand synthesis due to multiple initiations on the same negative-strand RNA or RF template. For flaviviruses, the ratio of positive-strand RNA to negative-strand RNA is about 10:1; for poliovirus it is about 40:1.

Initiation of positive-strand synthesis presumably occurs at the 3′ end of the negative-strand RNA. It is not clear if the negative-strand RNA template is single-stranded or in the duplexed RF. Furthermore, it is assumed that the mechanisms for initiation of positive-strand RNA synthesis require *cis*-acting determinants in the RNA and viral and cellular *trans*-acting factors and that these mechanisms and factors are, in part, distinct from those used for initiation of negative-strand synthesis. For togaviruses, negative-strand synthesis requires viral protein precursors in replication complexes (Sawicki and Sawicki 1994). When these precursors accumulate and are partially or fully processed, negative-strand synthesis ceases and positive-strand synthesis is initiated. For poliovirus, replication defects due to mutations in specific replication proteins can be rescued *in trans*, but only when the wild-type viral proteins are supplied in appropriate precursor form (Towner et al. 1999).

Assembly and release of virus particles

Once sufficient viral structural proteins have accumulated, nascent genomic RNAs can function as templates for translation and transcription and as substrates for encapsidation. For Kunjin virus, now considered a subtype of the flavivirus WNV (Scherret et al. 2001), translation is a prerequisite for replication of a nascent RNA, and replication is a prerequisite of encapsidation (Khromykh et al. 2001; Khromykh et al. 1999). The coupling of encapsidation to viral RNA synthesis may account, in part, for the fact that the encapsidation process is highly specific. Selection of a viral RNA for

packaging may also depend on the presence of a packaging signal in the RNA. Genomic RNA is selected for encapsidation even in the presence of a molar excess of subgenomic RNA in togaviruses. Sindbis virus contains a structural packaging signal in the 5′ region of the genome, within the coding region for nsP1. For picornaviruses only VPg-linked positive-strand RNA, and not viral mRNA, negative-strand viral RNA, or any cellular RNA, is packaged.

The morphogenetic pathway for formation of mature virions generally involves both assembly intermediates, or substructures, as well as precursor forms of the structural proteins. The first assembly intermediate in the poliovirus pathway, the 5S protomer, consists of one copy each of VP0, VP1, and VP3. Five protomers then assemble to form a pentamer (14S) and pentamers assemble into empty capsids. One assembly model predicts that the viral RNA is threaded into the empty capsid and the final morphogenetic step, cleavage of VP0 to VP2 and VP4, produces the fully mature, infectious virion. In an alternative model, 14S pentamers assemble with virion RNA to form provirions. This pathway suggests that empty capsids, found in infected cells, serve as storage units for 14S pentamers (Nugent and Kirkegaard 1995). For WNV, immature virions, with precursor forms of structural proteins, accumulate in vesicles and are then transported through the host secretory pathway. These precursor interactions may maintain structural proteins in stable conformations until assembly and release of new virions is complete.

Flavivirus virions are transported to the plasma membrane in vesicles and released by exocytosis. For the alphaviruses of *Togaviridae*, nucleocapsids interact with the host cell plasma membrane at sites occupied by viral transmembrane glycoproteins. This leads to binding of additional viral glycoproteins, wrapping of the membrane around the nucleocapsid (budding) and release of the enveloped particle (Garoff et al. 1998).

Coronavirus assembly initiates with binding of the N (nucleocapsid) protein via a specific signal located in the 3′ end of ORF 1b of the genomic RNA. Interaction between the nucleocapsid and the M protein, in the membranes of the ER and Golgi complex, triggers packaging. Virus budding take place in the budding compartment between the ER and Golgi when the E protein interacts with the M protein. Envelope glycoproteins, S and HE, are incorporated into virions through interactions with the M protein. Virions accumulate in secretory vesicles, which eventually fuse with the plasma membrane to release virus (Lai and Holmes 2001).

CONCLUSIONS

RNA viruses are inherently and uniquely interesting due to the fact that, unlike nearly any other biological agent or organism, their genetic blueprint is stored biochemically in the form of RNA instead of DNA. According to the central dogma of molecular biology, the flow of genetic information normally proceeds from DNA to RNA via transcription and from RNA to protein via translation. For positive-strand RNA viruses, this process is more direct since genomic RNA is messenger RNA and can be translated to protein upon release in the cytoplasm of the host cell. These viruses encode their own RdRp for RNA chain elongation activity, although formation of the replicase complex may include other viral as well as cellular factors.

A viral RNA-dependent RNA polymerase is intrinsically more error-prone than a DNA-dependent DNA polymerase and produces a population of viruses, referred to as a quasi species, characterized by members that are not genetically identical (Domingo and Holland 1997). Mutations in the coding region of viral genomic RNA, due to decreased fidelity of the viral polymerase, may be inconsequential, deleterious or even lethal, or may permit survival of the virus. For example, a random single-point nucleotide substitution in viral genomic RNA could result in one of the following five possibilities:

1. no change in amino acid due to redundancy of the genetic code
2. change to a different amino acid similar enough to be inconsequential to overall folding or function of the protein
3. change to a different amino acid dissimilar enough to diminish function due to alteration in protein conformation or catalytic site
4. change to a different amino acid that randomly confers functional benefit in a specific environment, due to improved conformation and/or catalysis, thus allowing survival of the mutant virus
5. change to create an early stop codon or eliminate an existing stop codon
6. no change or conservative change in amino acid with concomitant change in RNA secondary structure that is neutral, harmful or beneficial to function.

Similarly, mutations in the noncoding region of the viral genomic RNA can result in inconsequential, disadvantageous or advantageous functional modifications through alterations in *cis*-acting signals or specific RNA structures required for RNA–RNA or RNA–protein interactions. Thus, paradoxically, long-term survival of an RNA virus with limited coding capacity in a constantly evolving host is accomplished through accidental adaptive modifications that result from slightly unfaithful viral RNA replication by a viral-encoded error-prone polymerase.

INTRODUCTION

The DNA viruses exhibit diverse mechanisms of genome replication that are important to study for many reasons. Viruses provide useful models for the study of eukaryotic DNA replication because of their relative simplicity and ease of study; in fact, much of what we know about eukaryotic DNA replication has come from the study of viral systems. For instance, viruses that rely heavily on host-cell machinery for replication have provided experimental systems that have led to the identification of the components of the cellular replication machinery. Furthermore, viral enzymes involved in replication provide important targets for antiviral therapy, and the study of the mechanisms of viral DNA replication will therefore continue to provide vital information in the development of effective antiviral strategies. DNA viruses exhibit considerable diversity with respect to the molecular mechanisms of DNA replication. This is due to differences not only in genome size and structure but also in the location of viral DNA replication in the cell and the reliance on viral versus host enzymes. In this chapter we will consider DNA viruses of the following families: polyomaviruses, papillomaviruses, parvoviruses, adenoviruses, herpesviruses, and pox viruses (Table 1). While the polyoma- and papillomaviruses have circular genomes, the genomes of the other DNA viruses are linear. Among viruses with linear genomes, considerable diversity can be observed with respect to structure: single-stranded for the parvoviruses versus double-stranded for adenoviruses, herpesviruses, and pox viruses. Diversity in size is also apparent from less than 5 bp in the parvoviruses to approximately 200 kbp for the poxviruses. The diversity in size and structure of viral genomes has important implications in terms of mechanisms of DNA replication. For these reasons, in this chapter, replication strategies of each virus family will be considered separately. First, however, some guiding principles concerning DNA replication in general will be considered.

GENERAL PRINCIPLES OF DNA REPLICATION

DNA synthesis in viral as well as cellular systems involves the incorporation of deoxynucleosides in a template-directed process. Incorporation of deoxynucleosides invariably occurs onto the 3′ OH end of a growing DNA chain, resulting in a 5′ to 3′ polarity of elongation on the growing chain (Kornberg and Baker 1992). Replication generally begins at specific sites on viral genomes known as origins of replication, and many viruses encode specific origin binding proteins responsible for initiation of viral DNA synthesis (Stenlund 2003). DNA replication in DNA viruses is catalyzed by DNA-dependent DNA polymerases which in general require a free 3′ OH end in order to add deoxynucleosides. This is in contrast to DNA-dependent RNA polymerases and RNA-dependent RNA polymerases that are capable of initiating template-directed RNA synthesis de novo and do not require the presence of a free 3′ OH. One implication of this requirement is that viral

Table 1 *DNA viruses considered in this chapter*

Virus	Size of viral genome	Structure of viral genome	Location of replication	Replication proteins
Polyomavirus				
Simian virus 40	~5 000 base pairs	Closed circular double-stranded DNA	Nuclear	Viral and host
Papillomavirus				
Human and Bovine papillomaviruses	~8 000 base pairs	Closed circular double-stranded DNA	Nuclear	Viral and host
Parvovirus				
Minute virus of mice, Adeno-Associated Virus	~5 000 bases	Linear single-stranded DNA	Nuclear	Viral and host
Adenovirus				
Human adenovirus	~36 000 base pairs	Linear double-stranded DNA	Nuclear	Viral and host
Herpesvirus				
Herpes simplex virus type 1	~150 000 base pairs	Linear double-stranded DNA	Nuclear	Viral primarily (could be some host protein involvement)
Poxvirus				
Vaccinia virus	~200 000 base pairs	Linear double-stranded DNA	Cytoplasm	Viral

DNA replication is dependent on the presence of a primer; however, it is remarkable how different viruses have evolved novel strategies for priming DNA synthesis. Parvoviruses rely on structural features of the viral genome itself to prime new DNA synthesis whereas adenoviruses utilize a protein priming mechanism. Other DNA viruses utilize a strategy of formation of RNA primers similar to mechanisms used during cellular DNA replication. DNA synthesis for all DNA viruses requires the use of a DNA-dependent DNA polymerase; however, the smaller DNA viruses (polyoma-, papilloma- and parvoviruses) do not have the genetic capacity to encode a large number of viral proteins dedicated to viral replication. These viruses therefore utilize host-cell polymerases, while adenoviruses, herpesviruses, and poxviruses encode their own viral DNA-dependent DNA polymerases as well as additional replication proteins. Poxviruses are unusual in that DNA replication occurs in the cytoplasm and must therefore encode all enzymes and proteins needed for DNA replication.

As mentioned above, DNA replication generally begins at specific sites on viral genomes known as origins of replication with local unwinding or melting of the duplex to provide access to template strands (Stenlund 2003). Origins can increase the efficiency of DNA replication by directly or indirectly recruiting replication machinery leading to the assembly of multiprotein complexes needed for DNA replication. Given the complexity of the environment in which viral genomes replicate and the fact that viral genomes are present as single copy genomes within the host cell, it is important for sufficient concentrations of all of the essential factors to be brought together in one place. It would thus be expected that origin recognition proteins would exhibit highly specific DNA binding. In some systems this specificity is achieved by the initiator protein itself while in others a second viral or cellular protein increases specificity (Table 2).

Many viral origins consist of a core origin and auxiliary regions that are important for optimal viral replication. The core origins generally contain binding sites for viral initiator proteins and AT-rich sequences which facilitate melting during initial unwinding reactions. The auxiliary sequences enhance the efficiency of viral DNA replication and interestingly, often contain binding sites for cellular or viral transcription factors. The importance of auxiliary regions was originally discovered in polyoma viruses where the presence of the transcriptional enhancer stimulates DNA replication up to 1 000-fold; however, this has turned out to be a much more general phenomena (Table 2). The binding of transcription factors at origins of replication in many cases facilitates the rate limiting steps in the initiation process (Table 3). In some cases binding helps to recruit other replication proteins such as polymerases. In other cases, they help to change the activity of initiation proteins. Transcription factors can also cause changes in the global architecture or nucleosome structure of the origin. Thus, specific protein–DNA and protein–protein interactions are very important for initiation and recruitment of replication machinery to occur, and we will see many diverse examples in this chapter.

Table 2 *Viral DNA proteins that initiate and participate in DNA replication*

Virus	Origin binding protein(s)	Polymerase(s)	Other replication proteins
Polyomavirus			
Simian virus 40	Large T antigen (helicase activity)	Host cellular DNA polymerases α and δ	Many cellular: RPA, RF-C, RNase H, PCNA, Fen1, DNA ligase I
Papillomavirus			
Human and Bovine Papillomaviruses	E1 protein (helicase activity)	Host cellular DNA polymerases	Many cellular
Parvovirus			
Minute virus of mice	NS1 (helicase activity)	Host cellular DNA polymerases	RPA, PCNA
Adeno-associated virus	Rep 68, Rep 78 (helicase activity)		
Adenovirus			
Human adenovirus	DNA polymerase, preterminal protein complex	Viral	Viral SSB (DBP), Cellular proteins: transcriptional activators (NF1, Oct-1 and topoisomerase)
Herpesvirus			
Herpes simplex virus type 1	UL9, origin-binding protein (helicase activity)	Viral polymerase (UL30) and accessory protein (UL42)	Viral helicase-primase (UL5, UL8, and UL52), viral SSB ICP8)
Poxvirus			
Vaccinia virus	?	Viral	Several viral, no cellular

The binding of viral and cellular proteins at an origin of replication is followed by a melting or opening of the duplex. Once a region or regions of the origin are melted or distorted, recruitment of helicases and other replication proteins occurs (Waga and Stillman 1994). The function of the helicase is to unwind the DNA in advance of the replication fork (see Figure 1). Helicases translocate along single- or double-stranded DNA in an ATP-dependent fashion. Many DNA and RNA viruses encode helicases (Marintcheva and Weller 2001). The only DNA virus which does not encode its own helicase is adenovirus whose mechanism of replication does not require helicase activity.

In the simplest replication systems, replication proceeds by the formation of two replication forks which synthesize DNA in different directions from the origin (Kornberg and Baker 1992). This requires the use of leading- and lagging-strand DNA replication also known

Table 3 *Viral origin recognition proteins*

Virus	Initiator Protein	Binds specifically to ori	Melts ori	Other activities
SV40	Large T antigen	+	+	DNA-stimulated ATPase and helicase activities; recruits RPA, polα-primase, Topo I, and other cellular proteins
Adenovirus	pTP and DNA pol	+ (stimulated by cellular proteins Oct-1 and Nf-1)	+	Priming of DNA synthesis by protein priming
Herpes simplex virus	UL9	+	?	DNA-stimulated ATPase and helicase; binds ICP8 and the UL8 subunit of the viral helicase-primase
Papilloma viruses	E1 and E2	+	+	DNA-stimulated ATPase and helicase (E1); recruits RPA, polα-primase, Topo I, and other cellular proteins
Parvovirus MVM	NS1	+	–	Site-specific endonuclease; DNA-stimulated ATPase and helicase

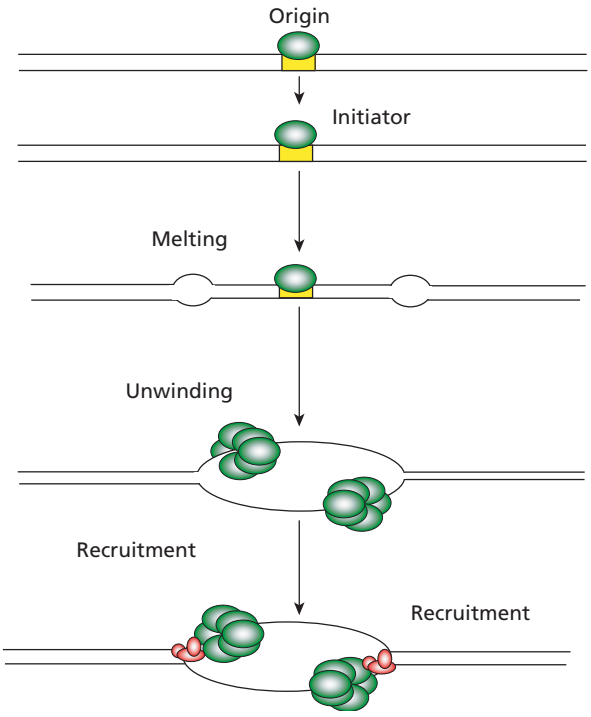

Figure 1 *Initiation of DNA replication. DNA replication generally initiates at an origin of replication in four distinct steps. The first step involves specific binding by an origin binding or initiator protein (initiator). In the example shown, specific binding is carried out by a single viral protein, but in some cases additional viral or cellular proteins are required for this initial binding event. In the second step, the initiator protein causes melting or distortion at the origin. The third step, helicase is loaded at the partially unwound origin and in the fourth step additional replication proteins are loaded. In the polyoma- and papillomaviruses, the initiator protein carries out all of these functions, binding, melting, unwinding, and recruitment. SV40 large T antigen and papilloma E1 proteins both form hexameric helicases which also carry out unwinding during the elongation step of DNA replication. (Adapted from Stenlund 2003)*

as discontinuous DNA synthesis (Figure 2). As mentioned above, all known DNA polymerases must elongate via addition of nucleoside monophosphates to an existing 3′ OH group resulting in DNA synthesis which proceeds in a 5′ to 3′ direction (Kornberg and Baker 1992; Depamphilis 1996). In order for a replication fork to move bidirectionally, both strands must be replicated by a mechanism that involves continuous synthesis on one strand (leading-strand DNA synthesis) and discontinuous synthesis on the other strand (lagging-strand DNA synthesis) (see Kornberg and Baker (1992) for detailed review). Lagging-strand DNA synthesis is accomplished by synthesizing short DNA fragments termed Okazaki fragments. Okazaki fragment synthesis involves first the synthesis of RNA primers; keep in mind that DNA-dependent DNA polymerases are not capable of de novo incorporation of deoxynucleosides into DNA. In order to produce the final DNA product, an enzyme which removes the RNA primers and a ligase

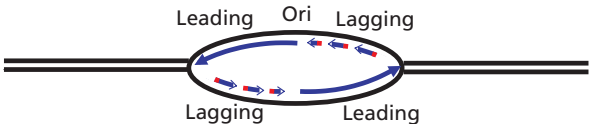

Figure 2 *Leading- and lagging-strand DNA synthesis. Since all DNA polymerases synthesize DNA only in a 5′ to 3′ direction, one strand (the lagging-strand) must elongate in the opposite direction from that of the movement of the fork itself. Lagging-strand DNA synthesis is accomplished by the synthesis of short DNA fragments termed Okazaki fragments. Okazaki fragment synthesis involves first the synthesis of a short RNA primer. In order to produce the final DNA product, an enzyme which removes the RNA primers and a ligase to repair the gaps between adjacent Okasaki fragments are needed. This mode of replication involving leading- and lagging-strand DNA synthesis is utilized by many replication systems including bacterial, eukaryotic, and many viruses. Black lines represent the parental duplex. Solid blue lines represent the nascent DNA strand and the red boxes represent RNA primers.*

to repair the gaps between adjacent Okasaki fragments are needed. This mode of replication involving leading- and lagging-strand DNA synthesis is utilized by many replication systems including bacterial, eukaryotic, and many viruses.

Some eukaryotic viruses have evolved unusual mechanisms for priming DNA synthesis. The parvoviruses have hairpin termini which are self-complementary and the 3′ termini can prime DNA synthesis. In adenoviruses, a protein is used to prime DNA synthesis. The first phosphodiester bond is formed between a nucleotide and a serine residue of the virally encode preterminal protein.

Several DNA viruses will be considered in this chapter including *Polyomaviridae, Papillomaviridae, Parvoviridae, Adenoviridae, Herpesviridae, and Poxviridae*. All of these virus families utilize the general principles of DNA replication, but each virus illustrates variations which serve to underscore the fascinating diversity among different viruses including genome size, strandedness, the use of novel methods for priming DNA polymerases, and intracellular localization.

POLYOMAVIRUSES

Polyomaviruses infect a wide variety of mammals and include four major species. A polyomavirus originally isolated from mice (murine polyomavirus (MPyV), simian vacuolating virus 40 (SV40) isolated from monkey kidney cells, and two human polyomaviruses, BK polyomavirus (BKPyV) (isolated from an immunosuppressed kidney transplant patient) and JC polyoma virus (JCPyV) from a case of progressive multifocal leukoencephalopathy. Because of the central role the polyomaviruses have played in our understanding of both viral and cellular DNA replications, this genus will be considered first. Because of the small size of

their genomes, their oncogenic properties and the existence of in vitro systems, polyomaviruses have been used extensively as models for eukaryotic DNA replication. Polyomavirus replicates lytically in mouse cells and causes abortive infections of rat and hamster cells in culture. SV40 replicates lytically in monkey and human cells but transforms rodent cells in culture.

General features of SV40 DNA replication

The *Polyomaviridae* have small circular genomes and replicate entirely by theta replication, resulting in interlocked circles that must be separated prior to genome encapsidation (Figure 3) (Depamphilis 1996). Polyomaviruses encode only one viral gene product responsible for DNA replication and rely on the host cellular machinery for the rest. SV40 will be discussed here as the best studied example of the polyomavirus family. The development of a reconstituted in vitro replication reaction capable of supporting SV40 DNA replication represented an important breakthrough in the study of chromosomal replication and allowed the identification of cellular proteins required for both SV40 and cellular DNA synthesis (Li and Kelly 1984; Waga and Stillman 1994). The detailed study of SV40 DNA replication has revealed many common elements between polyomavirus DNA synthesis and cellular DNA replication including chromatin structure, a common set of proteins comprising the replication machinery and the formation of replication forks which engage in bi-directional replication. In the early 1970s, electron microscopic analysis of replicating viral genomes revealed that SV40 DNA could initiate replication at a single site and that replication proceeded bidirectionally from this site. Replication bubbles could be observed which consisted of two replication forks moving in opposite directions. Bidirectional replication from a single origin was confirmed by elegant biochemical analysis (Hay and Depamphilis 1982). Another interesting feature of polyomavirus DNA replication is that it is tightly regulated; in fact, the study of how initiation and elongation are controlled provides insight into the mechanisms of how eukaryotic DNA replication is regulated.

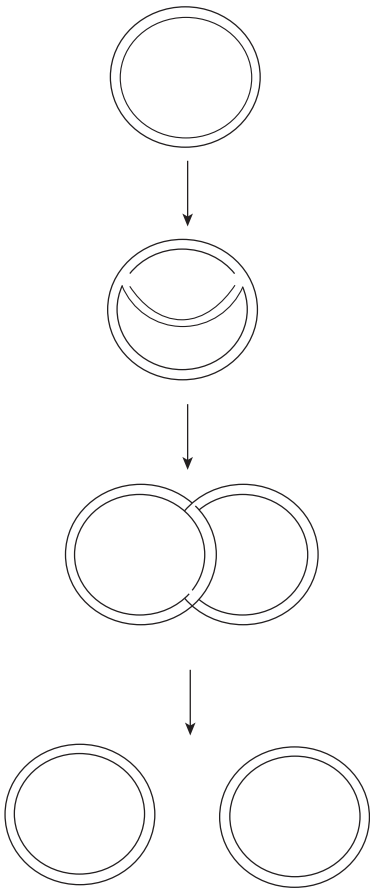

Figure 3 *Theta structure DNA replication. In this mode of viral DNA synthesis, double-stranded circular DNA replicates by bidirectional DNA synthesis in opposite directions from the origin of replication. When the forks meet at a point on the genome diametrically opposite to the origin of replication. This results in the formation of a two interlocking daughter molecules. The catenated circles can be resolved into monomer circles by a topoisomerase activity.*

SV40 GENOME

The SV40 viral genome consists of a single double-stranded circular supercoiled DNA molecule approximately 5 kbp in size (Depamphilis 1996). The genome is complexed with histones both in virions and in infected cells, and the chromatin structure is believed to be similar if not identical to host DNA: four cellular histones H2A, H2B, H3, and H4 are associated with viral DNA. The origin of replication of SV40 is surrounded by noncoding regions which control transcription of early and late genes which are transcribed in opposite directions (Figure 4). The early genes of the SV40 encode 'T antigens' – proteins that can be detected by sera from animals bearing SV40-induced tumors. SV40 encodes large and small T antigen while murine polyomavirus encodes small, middle, and large T antigens. These proteins have common N-terminal regions but unique COOH-termini derived from alternative splicing patterns. The only viral protein believed to play a direct role in viral DNA replication is the large T antigen, a multifunctional protein of approximately 90 kDal known to be involved in regulation of transcription, DNA replication, and morphological transformation. The late genes of SV40 encode structural proteins VP1, VP2, and VP3.

At the earliest stages of infection of human or monkey cells, early transcription results in the synthesis of both large and small T antigens. Large T antigen localizes primarily to the nucleus and acts to induce

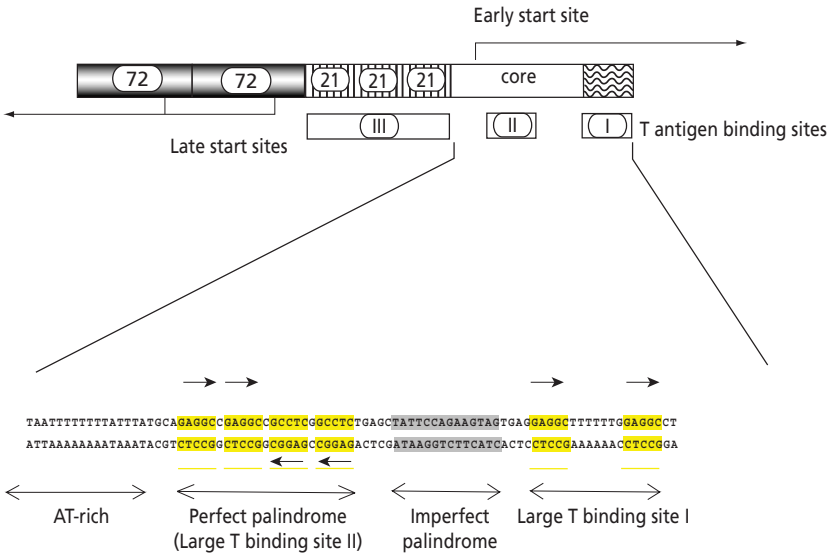

Figure 4 *Regulatory regions of SV40. The control region of gene expression in SV40 is shown here. Early and late genes are transcribed in opposite directions. This region contains an origin of DNA replication as well as binding sites for large T antigen. The 72-bp enhancer sequences and the 21-bp repeats are signals which enhance transcription in this region. The minimal origin region is shown below consisting of an AT-rich region, the large T binding site II, an imperfect palindrome and large T binding site I. The pentameric T antigen binding sites are shown in yellow.*

expression of S phase specific cellular genes thereby causing cells to enter S phase. Large T antigen has several functions including down regulation of its own transcription and initiation of viral DNA replication. Once DNA synthesis has initiated, late viral gene expression and assembly of virions proceeds. The binding of large T antigen to the SV40 origin of replication is a critical step and the subject of intensive study.

Origin of replication

As described above, viral origins of replication are discrete DNA segments containing specific sequences to which viral initiator proteins can bind and generally consist of a core region flanked by surrounding auxiliary sequences that can enhance the efficiency of viral DNA replication (Depamphilis 1996; Stenlund 2003). The importance of auxiliary regions was originally discovered in polyomaviruses, but the utilization of auxiliary regions has now turned out to be a general phenomena.

The SV40 origin of replication consists of a core origin region of 64 bp and an extended region containing an enhancer (72 bp) and a series of Sp1 binding sites (21 bp) (Figure 4) (Depamphilis 1996). The core region contains a 17-bp AT-rich element, four GAGGC pentanucleotides to which large T antigen binds and the early palindrome (EP). The four pentanucleotides (T antigen binding site II) are arranged as inverted pairs that serve as binding sites for T antigen. The binding of T antigen to site II is believed to bend the DNA. The AT-rich region and the 10-bp early imperfect palindrome are also essential for DNA replication. The AT-rich element is known to undergo bending independent of protein binding. The AT track can also bind cellular factors such as the transcription factor Oct1. The flanking regions also contain binding sites for cellular transcriptional activators. A second T antigen binding site to the right, site I, is not essential, but can stimulate the efficiency of viral DNA replication in vivo. Other flanking sequences to the left include three copies of the 21-bp repeats containing binding sites for the cellular transcription factor Sp1 and two copies of the 72-bp enhancer. The start sites for the early and late mRNAs are also shown. As will be seen later in this chapter, origins of replication are often situated between promoters, emphasizing a very close relationship between the regulation of transcription and the initiation of viral DNA replications.

Large T antigen

SV40 large T antigen is a 708-aa phosphoprotein that plays multiple functions during the SV40 life cycle. T antigen localizes primarily in the nucleus and in addition to its role in initiation and elongation of viral DNA synthesis it can drive the infected cell into S phase, cause morphological transformation, down-regulate its own transcription, and stimulate late transcription (Fanning and Knippers 1992; Simmons 2000). During DNA replication, T antigen binds the SV40 origin of DNA replication in a sequence-specific manner and its helicase activity unwinds the duplex in an ATP dependent fashion. It is also capable of recruiting cellular replication proteins to the origin through protein–protein interactions. Numerous post-translational modifications have been reported for T antigen including

phosphorylation, glycosylation, adenylation, ADP ribosylation, and acylation. It is one of the best studied viral proteins and a large database of mutations that alter various activities of T antigen has been compiled (Fanning and Knippers 1992; Simmons 2000; Ott et al. 2002).

Considerable effort has been given to understanding the structure and function of the 708 residues of SV40 large T. The domain structure of this multifunctional protein is now becoming more clear (Fanning and Knippers 1992; Simmons 2000; Ott et al. 2002; Li et al. 2003a). A minimal sequence-specific DNA binding domain lies in the middle of the protein residues 131–260. The solution structure of the DNA-binding domain has been solved (Li et al. 2003a); interestingly, it is similar to the minimal DNA-binding domain of the papillomavirus replication helicase, E1, described below. Of note is that considerable structural similarity exists despite only an approximately 6 percent identity in the primary amino acid sequence between the two initiator proteins (Li et al. 2003a; reviewed in Stenlund 2003). A zinc-binding domain lies downstream of the DNA-binding domain. The ATPase/helicase domain has been mapped to the C terminus (residues 131–616), and other functional domains which have been mapped include the J domain and binding sites for the cellular cell cycle regulatory proteins Rb and p53.

Mechanism of SV40 DNA synthesis

The binding of an initiator protein to a specific origin of replication is a common theme in the replication of DNA viruses (Depamphilis 1996; Stenlund 2003). A generic reaction of this type is shown in Figure 1 in which the initiation process is divided into four separate steps, recognition, melting, unwinding, and recruitment of replication factors.

Initiation At the outset of viral DNA replication, T antigen binds specifically to the SV40 origin of replication as a monomer. In the presence of ATP, individual monomers of T antigen assemble into a single hexamer. In addition to the pentanucleotide binding sites, the EP region is required for hexamer formation. A second hexamer then forms over the origin which causes two types of structural changes: the EP region is melted and the AT track is distorted or twisted (Depamphilis 1996). Following this structural distortion at the origin, T antigen functions as a helicase to unwind the duplex DNA in a reaction which involves ATP hydrolysis. The actual initiation of viral DNA synthesis requires the recruitment of three cellular proteins to the unwound origin: replication protein A (RPA), DNA polymerase α-primase and topoisomerase I (topo I) (Simmons et al. 1996; Gai et al. 2000). T antigen is known to bind RPA and it is believed that DNA unwinding by T antigen produces single-stranded DNA; the interaction between T antigen and RPA results in loading of RPA onto the single-stranded DNA (Figure 5). The DNA polymerase α-primase is responsible for the synthesis of Okazaki fragments. Polymerase α-primase binds specifically to both the RPA and large T antigen assembled at the origin (Ott et al. 2002). Once bound, the primase initiates synthesis of the leading strands by producing RNA primers that can be extended as DNA by polymerase α. Topo I is believed to nick and religate DNA at the origin to relieve torsional strain ahead of the replication fork (Waga and Stillman 1994).

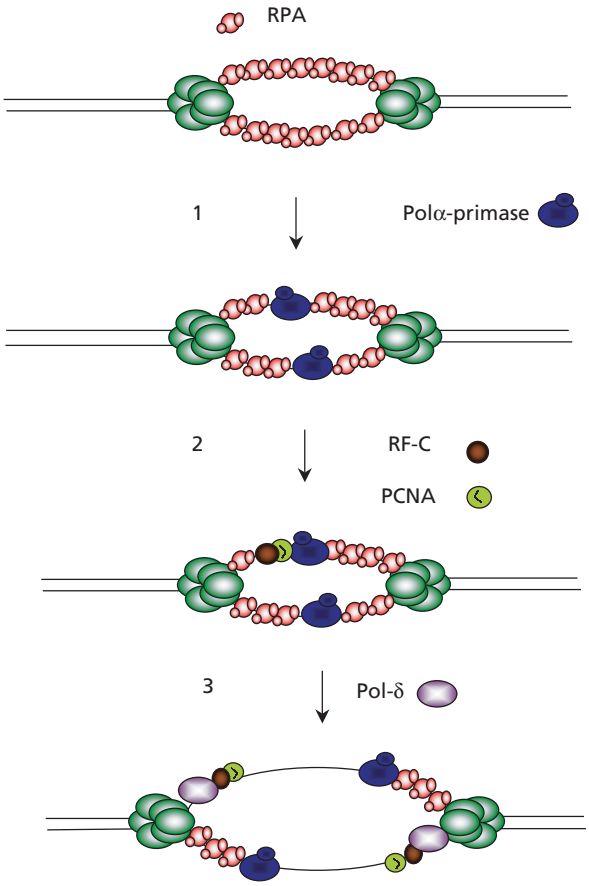

Figure 5 *SV40 DNA synthesis. Large T antigen (also depicted in Figure 1) recruits cellular proteins to the unwound origin of replication. Once RPA and polymerase α-primase are recruited by T antigen, synthesis of the leading strands is initiated by producing RNA primers which can be extended by pol-α creating an RNA-DNA fragment of approximately 30 nucleotides (Step 1). RF-C binds to the 3′ OH of the RNA-DNA fragment in a reaction that requires ATP hydrolysis. RF-C can load PCNA onto the template (Step 2). DNA pol-δ is then recruited and binds to the PCNA–RF-C complex (Step 3). The complex is now able to carry out leading and lagging-strand DNA synthesis.*

Elongation The 3′ OH of the nascent RNA–DNA fragment (about 30 nucleotides) can then be recognized by the replication factor C (RF-C). RF-C promotes the ATP-dependent loading of PCNA onto the template which is followed by the recruitment of DNA polymerase δ. Although pol δ is sufficient for continuous

leading strand DNA synthesis in an in vitro reconstitution experiment, in vivo another cellular polymerase, pol ϵ, appears to be required in addition. Lagging-strand synthesis initiates on the opposite strand again through the action of DNA polymerase α-primase. Thus, leading-strand and lagging-strand replication occurs at each replication fork in the bidirectional origin of replication. The classic problem of how a single replication fork apparatus can synthesize DNA in opposite directions at the same time was solved by the proposal that the template DNA for discontinuous synthesis can be spooled through an immobile replication complex containing all proteins necessary for synthesis of both leading and lagging strands (Wessel et al. 1992; mechanism reviewed in Stenlund 2003). Spooling has been observed by electron microscopic analysis. The DNA fragments produced by lagging-strand synthesis are sealed in a reaction that involves removal of the primers by RNase H (specifically degrades RNA from RNA–DNA hybrids) and the 5′–3′ exonuclease *Fen*1. The gaps can then be repaired by DNA polymerase δ and the ends of the DNA fragments joined by DNA ligase I. When replication gets to a point on the circular molecular opposite from the origin of replication, the reaction is terminated in a reaction which involves topoisomerases I and II. These enzymes remove torsional stress which accumulates through the action of the helicase unwinding DNA ahead of the growing fork. Topoisomerase II mediates the separation of the two intertwined (catenated) daughter molecules by the passage of one through the other. Table 4 lists the functions of each of these cellular proteins. As mentioned above, it was through the analysis of an in vitro reconstitution experiment with SV40 and large T antigen that the components of the cellular machinery were first identified (Li and Kelly 1984).

When these viruses infect permissive hosts, they initiate a productive cycle of infection; however, there are some cell types that do not support productive infection. Instead, in these cells the viral DNA becomes integrated into that of the host cells, in many cases transforming them. This is known as morphological transformation and occurs through the interaction of viral and cellular proteins (Simmons 2000).

PAPILLOMAVIRUSES

The papillomaviruses are a large family of small double-stranded DNA which are closely related to the polyomaviruses but differ in several important ways (Depamphilis 1996). Papillomaviruses infect mucosal or cutaneous epithelia causing warts and cervical carcinoma. Most of the initial work on DNA replication of these viruses was performed with Bovine papillomavirus

Table 4 *Cellular proteins required for SV40 DNA synthesis*

Cellular protein	Molecular mass (kDal)	Function
RPA	70	Binds single-stranded DNA; promotes origin unwinding; stimulates pol-α:primase; cooperates with RF-C and PCNA to stimulate DNA pol-δ
	32	
	12	
DNA pol-α: primase	180	Initiates leading- and lagging-strand synthesis through the synthesis of RNA primers and Okazaki fragments
	70	
	58	
	48	
RF-C	140	Auxiliary factor for DNA pol-δ and -ϵ; loads PCNA onto DNA; DNA-dependent ATPase
	40	
	38	
	37	
	36.5	
PCNA	36	Processivity factor for DNA pol-δ and -ϵ
DNA pol-δ	125	Completes leading- and lagging-strand synthesis; processive when bound to PCNA
	48	
DNA pol-ϵ	255	DNA polymerase which may complete lagging-strand synthesis
	55	
Topoisomerase I	110	Relieves torsional strain in front of replication forks
Fen1	48	5′ to 3′ exonuclease; removal of RNA primers
RNase H1	89	Endonuclease; cleaves RNA primer
DNA ligase I	125	Ligates Okazaki fragments

(BPV) which has served as a prototype for the papillomaviruses. Recent work with human papillomavirus (HPV) has revealed similarities and differences between BPVs and HPV. Examples from both replication systems will be discussed in this chapter.

General features of papillomavirus DNA replication

Papillomaviruses can be distinguished from polyomaviruses by exhibiting a more complex pattern of replication governed by the differentiation stage of the infected cell. In fact, the life cycle of papillomaviruses is known to be tightly coupled to the cellular differentiation program of the epithelium (Longworth and Laimins 2004). DNA replication actually occurs in three different stages. Three different modes of DNA synthesis during different stages of infection of skin have been reported: amplification, maintenance, and productive replication. The virus first infects proliferating basal epithelial cells, and in these cells the genome enters the nucleus and is amplified as a circular genome to a concentration of approximately 50–100 copies per cell. This replication requires the viral proteins E1 and E2 as well as the cellular replication machinery. This stage is believed to occur by theta mechanism and therefore resembles SV40 DNA replication. These circular DNA episomes are then maintained by a regulated process in which the episomes are replicated once per cell cycle again using an SV40-like mechanism. The final productive stage of DNA replication occurs in the outer layers of the epidermis, in differentiated cells. The shift from maintenance to productive replication is not well understood, but may involve a transition from SV40-like theta replication to a rolling circle mechanism of replication (Flores and Lambert 1997). DNA synthesis during the maintenance and the final productive stage of DNA replication also utilizes E1, E2, and the cellular DNA replication machinery (Broker and Chow 2001; Stenlund 2003). The fact that the productive phase of viral DNA replication occurs in terminally differentiated epithelial cells presents an interesting dilemma in that the cellular replication machinery required for viral replication would not be expected to be present in noncycling terminally differentiated cells (Broker and Chow 2001). Cellular replicative proteins are generally turned off in such cells. During the productive phase of the viral life cycle, papillomaviruses are presumed to be able to induce S-phase-specific viral functions. The viral protein E7 is required for productive infection in these differentiated cells and is believed to function by inducing the synthesis of the cellular replication proteins (Cheng et al. 1995; Broker and Chow 2001). Cellular proteins such as polymerase α and PCNA are likely induced in a manner similar to induction of host DNA synthetic machinery by SV40 T antigen.

The ability to induce the expression of S-phase-specific cellular genes is shared by several DNA viruses. The transcription of such cellular genes is tightly regulated by the Rb-E2f complex (Munger et al. 1989). E2f proteins are transcriptional regulators which bind cellular promoter sequences and stimulate transcription of S-phase-specific cellular genes. The presence of Rb in the E2f complex results in repression of these cellular genes. During the progression into S phase, Rb is phosphorylated resulting in its release from E2f and the induction of cellular genes encoding replication proteins such as histones and polymerases. Several viral proteins including adenoviral E1A, SV40 large T, and the E7 proteins of some human papillomaviruses have been shown to bind to the region of Rb that contacts E2f thereby resulting in activation of the E2f transcription factor. Thus, during productive papillomavirus infection, the E7 protein can stimulate the expression of the cellular DNA synthetic machinery. Following the replication of viral genomes, late viral proteins such as capsid proteins are made and progeny virus are assembled and eventually shed. These stages of replication are believed to be tightly regulated.

PAPILLOMAVIRUS GENOME

The papillomavirus genomes are small double-stranded DNA molecules of approximately 8 kbp (larger than the closely related polymaviruses) (Depamphilis 1996). All ten open reading frames are located on one strand of the viral DNA and all transcription is in a clockwise direction. Open reading frames are designated as either early (E) or late (L) based on their location on the genome. The early region encodes regulatory proteins which are expressed in nonproductively infected cells and also in cells transformed by papillomaviruses. Early genes *E1* and *E2* are required for DNA synthesis (reviewed in Stenlund 2003). At least five other early genes expressed from differentially spliced and partially overlapping mRNAs play various roles in regulation of gene expression and transformation. The late genes *L1* and *L2* encode structural proteins for the viral capsid and are only expressed in productively infected cells.

Origin of replication

The papillomavirus origin of replication lies in a small fragment located between the early open reading frames and a region called the long control region which contains regulatory signals for viral transcription (Stenlund 2003). Thus, as with the polyomaviruses, a relationship between the origin and binding sites for transcription factors exists (Depamphilis 1996). In the case of the papilloma viruses, the definition of the core origin is complicated by the apparent redundancies in this region. In the BPV ori, the core ori is contained in a fragment containing an AT-rich region, a binding site for E1 and

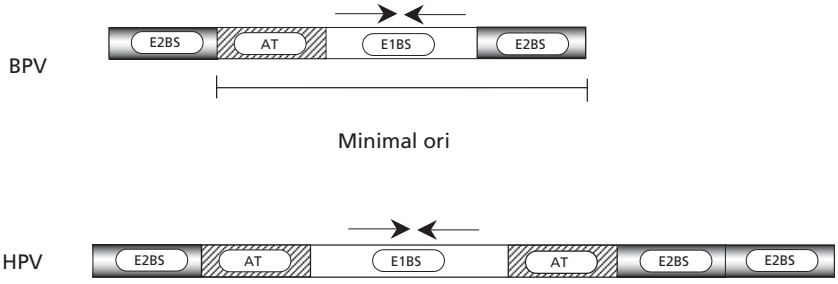

Figure 6 *Origin region of papillomavirus. BPV origin contains an AT rich region and a palindromic binding site for the initiator protein E1. However, these two elements are not sufficient for even minimal origin activity which requires at least one binding site for the transcription factor E2. In this case the E2 activator is required for loading of E1 to the origin (see text). In the HPV type origins, two binding sites for the E2 transcription factor are apparently required.*

a binding site for E2 to the right (Figure 6) (Chen and Stenlund 2002). However, if the right hand E2 binding site is deleted, replication can occur if the left hand E2 binding site is present. The HPV type origin contains a binding site for the viral replication initiator E1, three copies of a binding site for the viral transcriptional activator E2 and two AT-rich sequences. Thus, as with the polyomavirus origins of replication, both the BPV and HPV origins contain core essential elements flanked by auxiliary sequences which appear to enhance replication activity (Depamphilis 1996).

Replication proteins E1 and E2

E1 is the only viral protein that is directly involved in DNA replication. E2 is a transcription protein which greatly stimulates E1 binding at the origin. E1 proteins from both BPV and HPV share similarities with SV40 large T antigen (Enemark et al. 2000; Hickman et al. 2002). The BPV E1 protein is a 68-kDa nuclear phosphoprotein that binds specifically to the origin of replication. E1 has DNA-dependent ATPase and DNA helicase activities and binds to the origin of replication with weak affinity. E1 also interacts with cellular replication proteins such as the large subunit of DNA polymerase α (reviewed in Broker and Chow 2001). E2 interacts with E1 and facilitates E1 binding to the origin. E2 may also stimulate viral DNA replication by interacting with cellular proteins recruited to the origin such as RPA. E2 also plays a role in genome maintenance.

Mechanism of papillomavirus DNA replication

Initiation Much of the analysis of papillomavirus initiation has been performed in the BPV system. The availability of an in vitro system in which viral DNA replication occurs in a cell-free extract has been very valuable in our understanding of events which occur during the initiation of DNA replication. It should be kept in mind, however, that such in vitro reactions do not always accurately mimic events which occur in vivo. E1 and E2 proteins interact with one another and form a complex at the viral origin of replication. E1 is related in sequence and possesses activities analogous to the SV40 large T antigen such as ATPase, helicase, origin binding, and unwinding (Hickman et al. 2002; Stenlund 2003). BPV type 1 E1 binds to an 18-bp inverted-repeat element within the origin DNA with low specificity (Chen and Stenlund 2002). E2 is a dimeric transcription-replication factor that also binds to the origin. E1 and E2 bind cooperatively to the origin of replication to form an active initiation complex. The E2 protein is believed to act as a clamp-loading protein that stabilizes the E1-origin interaction and increases its specificity. A dimer of E1 is first bound together with a dimer of E2 ($E1_2E2_2$) (Chen and Stenlund 2002; Enemark et al. 2000). Binding of a second dimer of E1 occurs by displacing the E2 dimer in an ATP-dependent fashion creating a tetramer of E1. A bend is induced in the DNA by these interactions. Additional monomers of E1 are recruited to the complex eventually forming a hexamer and a double hexamer of E1 at the origin. ATP is required for the formation of the higher order structures. Cell cycle-specific phosphorylation may also be important in this assembly process (Broker and Chow 2001).

The formation of the initiation complex in HPV may differ slightly from BPV in some details; for instance, the HPV-1 E1 appears to be able to bind ori in a stable manner and to initiate replication on its own, at least in vitro. On the other hand, recent evidence suggests that the E1/E2 ratio is important for HPV replication efficiency and that regulation of E1 and E2 protein expression may be important for regulation during various stages of the virus life cycle.

E1 hexamers or double hexamers assemble at the origin, and it is this larger oligomer of E1 that is active in melting or distorting the duplex DNA (Stenlund 2003). This melting step is distinct from the ATP-dependent unwinding which occurs later. Melting is a change in the conformation of the DNA and can be observed by reactivity with single strand-specific agents such as permanganate ions which are able to modify non-base-paired resides. This melting or distortion step is

analogous to that described above for melting at the SV40 origin. Once a small region of single-stranded DNA is generated, RPA is recruited and melting occurs. The actual unwinding step involves the double hexamer which is now believed to form a bidirectional helicase. As with SV40, although the two hexamers are believed to unwind DNA in opposite directions, they appear to be held together. A new model for replication is emerging which suggests that instead of the hexameric helicases moving along the viral DNA template during replication in opposite directions, the template is actually drawn through the double hexamer as the DNA is unwound (reviewed in Stenlund 2003). The notion of a helicase which functions by 'pumping' DNA through a double hexamer is not unique to the E1 protein. Similar mechanisms have been proposed for SV40 T antigen and for the *E. coli* replicative helicase DNA B.

Elongation Little is known about the actual elongation phase of papillomavirus DNA replication. The early stages of DNA replication appear to occur by theta replication, however, it is possible that a switch from theta to rolling circle replication occurs during productive DNA replication (Flores and Lambert 1997). As in SV40 DNA replication, the E1 helicase is presumed to be the replicative helicase (Broker and Chow 2001). E1 also interacts with the polymerase α primase complex. Bidirectional DNA synthesis utilizes the cellular DNA synthetic machinery. In addition to RPA and the polymerase α primase complex, PCNA, RF-C, DNA polymerase δ or ϵ, and topisomerases I and II are presumably needed for papillomavirus DNA replication (reviewed in Broker and Chow 2001).

PARVOVIRUSES

The *Parvoviridae* are the smallest of the eukaryotic DNA viruses with genomes consisting of linear single stranded DNA molecules of 4 500–5 000 nucleotides. These viruses have been classified as either nondefective or autonomous parvoviruses, genus *Parvovirus*, such as the minute virus of mice (MVM), or defective or dependent parvoviruses, genus *Dependovirus*, such as the adeno-associated viruses (AAV) which rely on coinfection with adenovirus or herpesviruses for productive infection. Members of the autonomous *Parvovirus* genus can replicate productively without the aid of a helper virus. Replication of the autonomous parvoviruses requires that the infected cell enter S phase, since this virus utilizes components of the cell DNA replication machinery for its own replication; however, in contrast to SV40, these viruses cannot induce resting cells to enter S phase. As a result, productive infection is restricted to proliferating cells (Berns 1990; Depamphilis 1996).

General features of parvovirus DNA replication

Parvoviral DNA replication is similar to replication strategies of single-stranded coliphage genomes from bacteria (Berns 1990). The general mechanism has been called a 'rolling hairpin.' The incoming single-stranded DNA molecules form secondary structures at the termini which provide a 3′ OH primer for complementary strand synthesis. A linear duplex intermediate with one covalently closed end is generated. The resolution of this end by a site-specific nick results in the regeneration of the genomic termini. Again, the terminal redundancy can lead to another hairpin which can be elongated to make a double-stranded dimer molecule. Viral DNA replication proceeds through a series of concatemeric duplex intermediates by a strand displacement mode of synthesis involving leading-strand synthesis only. The autonomous and dependent parvoviruses share several features, but differ in some important respects. Both AAV and MVM have palindromic ends, but in MVM, the ends are not identical. Another difference is that in MVM, only the minus or noncoding strand is packaged.

MVM GENOME AND ORIGINS OF REPLICATION

The negative-sense MVM genome is approximately 5 200 bp long and exists primarily as a single-stranded DNA with terminal palindromic units which are predicted to form hairpin and other secondary structures. These terminal palindromic regions act as viral origins of replication during the process of regeneration of terminal sequences from long concatamers (termed junction resolution). They also play a unique role in the rolling hairpin replication mechanism used by this virus (described below) (Berns 1990).

MVM GENE PRODUCTS

The genome encodes two structural proteins VP1 and VP2; a third virion protein VP3 is present in infectious particles and derives from a proteolytic cleavage from VP2. The virus also encodes two nonstructural proteins, NS1 and NS2. NS1 is involved in both viral DNA replication and the transactivation of structural protein expression (Cotmore et al. 1995; Christensen and Tattersall 2002). NS1 is a site-specific nickase, recognizing the origin sequences present in the two viral termini and has been shown to nick and resolve these concatemers into unit length molecules suitable for packaging. The NS1 molecule becomes bound at the 5′ end of the viral DNA after nicking. It also comprises a 3′ to 5′ helicase, similar to the SV40 T antigen and papillomavirus E1 (reviewed in Marintcheva and Weller 2001). Alternate splicing events result in the production of three different versions of NS2 which differ in their C-terminal

sequences. NS2 may be involved in DNA replication, although its role is not clear at this time.

Mechanism of replication

Parvoviral DNA replication utilizes a modification of rolling circle replication mechanism dubbed rolling hairpin synthesis (Berns 1990). The genome is replicated through a series of monomeric and concatemeric duplex replicative-form (RF) intermediates. Replication proceeds unidirectionally by leading-strand continuous synthesis of DNA. The incoming viral genome is a linear single-stranded DNA molecule; however, the palindromic origin regions are believed to adopt secondary structures which may be simple hairpins or more complex T- or Y-shaped structures. The ability of the 3′ end to base pair within the terminal palindrome results in the formation of an ideal template-primer structure for the initiation of DNA replication (see Figure 7) (Berns 1990). This molecule is converted into a double-stranded intermediate by extension of the 3′ end by the cellular replication machinery resulting in a linear duplex intermediate, the original right-end hairpin is unfolded and copied to form a duplex terminal palindrome. In this model, the unidirectional replication fork shuttles back and forth along the linear genome. This mechanism involves unfolding and refolding of the two palindromic viral termini in such a way that the advancing replication fork can switch directions backwards and forwards generating a series of dimeric and tetrameric replication intermediates. Duplex copies of the unit-length genome become linked in head-to-head and tail-to-tail configurations.

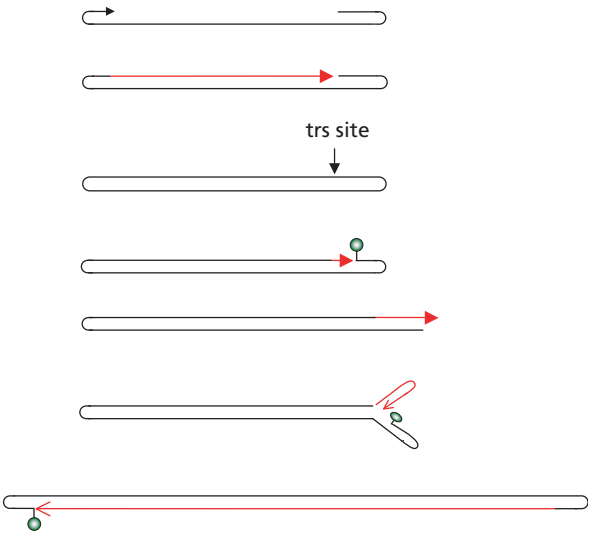

Figure 7 *Model for MVM DNA replication. The 3′ terminus of the virion strand is thought to fold back on itself to provide a primer for initiating synthesis of the complementary strand. When DNA synthesis reaches the right end, it is thought that a ligation event produces a linear duplex molecule with covalently closed termini. The right end can then be nicked by NS1 and the protein becomes covalently associated with the 5′ end, leaving a 3′ OH that copies the right end to a duplex extended form. The right end undergoes a conformational change resulting in the formation of a double hairpinned molecule which can be extended by further DNA synthesis. A dimer molecule is generated in which the monomer viral genomes are inverted with respect to one another. Terminal resolution and strand exchange leads to different orientations of the terminal sequences and eventually one strand is packaged into progeny genomes.*

Initiation The viral NS1 protein plays a vital role in this mechanism by recognizing origin sequences present in the two viral termini (Cotmore et al. 1995). NS1 recognizes a specific site in the origin region and introduces a nick at an adjacent initiation site. The minimal core origin is approximately 50 bp long and contains three distinct recognition sequences. NS1 binds site specifically to the (ACCA)2 repeat motif in an ATP-dependent manner. Although NS1 can bind by itself, nicking does not occur unless a cellular factor, called parvovirus initiation factor (PIF) is also present. Together, PIF and NS1 form a high-affinity ternary complex capable of nicking and subsequently initiating replication at the origin (Christensen and Tattersall 2002). After nicking, NS1 remains covalently attached to the 5′ end of the nicked DNA thereby freeing the 3′ hydroxyl group to act as a primer for DNA synthesis. The NS1 molecule bound at the 5′ end may also serve as a 3′ to 5′ helicase. Interestingly, it has recently been shown that similar to the SV40 T antigen, NS1 can be regulated by post-translational modification such as phosphorylation. Modification by phosphorylation of NS1 regulates the site-specific binding and DNA unwinding activities of the viral polypeptide (Nuesch et al. 2001). These phosphorylation events also determine the ability of NS1 to nick the left-end MVM origin site-specifically and control strand-displacement synthesis through its progressive helicase function. Multiple cellular kinases are believed to be responsible for these phosphorylation events (Nuesch et al. 2001).

Elongation DNA replication occurs through a series of monomeric and concatemeric duplex replicative-form intermediates and DNA synthesis by a unidirectional, leading-strand-specific process. The other cellular proteins required for MVM replication are also consistent with a leading-strand synthesis mechanism of DNA replication including RPA and proliferating cellular nuclear antigen (PCNA) (Christensen and Tattersall 2002). Although the cellular polymerase involved in vivo MVM DNA replication has not been identified, a processive leading-strand synthesis reaction has been reconstituted in vitro on a PIF-NS1 initiated origin by the addition of recombinant RF-C, PCNA, RPA and pol δ (Christensen and Tattersall 2002). RF-C is expected to act as a clamp loading protein recognizing the primer-template junction and loading PCNA onto the template to form a sliding clamp which stabilizes DNA poly-

merase on the template thereby promoting processive chain elongation. Enzymes identified in the SV40 DNA replication system which are involved in the generation or processing of lagging-strand Okazaki fragments (polymerase α-primase, RNase H, ligase I, and MF-I) have not been implicated in parvovirus replication.

ADENO-ASSOCIATED VIRUS (AAV)

In contrast to the MVM autonomous replicating parvovirus, AAV generally requires a co-infecting virus to efficiently replicate. Interestingly however, under conditions of genotoxic stress, AAV is capable of replicating in the absence of helper virus suggesting that whatever functions are provided by the helper viruses can be mimicked in the cell under certain kinds of stress conditions (Yakobson et al. 1989).

AAV genome and origin

Like MVM, AAV is a single-stranded DNA (ssDNA) virus whose genome is approximately 5 kbp and contains inverted terminal repeat (ITR) structures at each end. Trs can self-anneal to form terminal hairpinned structures and serve an important role as primers for DNA synthesis using host-cell synthetic machinery. In addition to containing an origin of replication, TRs also contain the packaging signal and the *cis*-acting elements needed for chromosomal integration (Berns 1990; Im and Muzyczka 1990).

AAV proteins

The 4.7 kbp ssDNA genome of AAV has two open reading frames, rep and cap (Im and Muzyczka 1990). Four viral proteins are encoded by the rep genes, two larger proteins, Rep68 and 78 and two smaller proteins, Rep52 and Rep40. These four gene products are produced by differential use of promoters: Rep68 and 78 are translated from mRNAs initiating at the one viral promoter, and the smaller proteins are translated from mRNAs that originate from another promoter. Differential splicing accounts for the differences between Rep68 and 40 and their longer counterparts, Rep78 and Rep52. Rep 68 and Rep78 are multifunctional proteins involved in DNA replication, transcription, packaging, and proviral integration (Li et al. 2003b). Rep68 and Rep78 exhibit several activities including sequence-specific double-stranded DNA binding, site-specific, single-stranded DNA endonuclease activity and ATP-dependent DNA helicase activities. Interestingly, the smaller Rep proteins 52/40 have been shown to play a role in packaging and this role is inhibited by the larger Reps78/68. In the case of MVM, there are no smaller versions of NS1, and it is not clear how regulation between replication and packaging occurs.

Mechanism of replication During AAV DNA replication, Rep68 and 78 bind viral Trs and induce a site-specific, single-stranded nick. Rep is thought to form oligomeric structures when bound to DNA containing a specific DNA-binding site (RBE) (Li et al. 2003b). Although a dimer of rep is believed to be required for trs nicking activity, it is thought that larger oligomeric structures then form on DNA, the largest of which appears to contain six Rep molecules (Li et al. 2003b). ATP may stimulate the formation of these higher order structures. A higher order structure containing six Rep molecules is reminiscent of other viral replication proteins which form hexamers upon binding their DNA substrates including SV40 large T antigen and papillomavirus E1 protein (Stenlund 2003; Hickman et al. 2003).

Initiation of replication Replication of AAV is initiated from the 3′ hairpin primer of the single-stranded input genome. The hairpin exposes a 3′ hydroxyl primer that can be extended by host–cell polymerase to initiate viral DNA synthesis a linear duplex molecule in which one of the ends is covalently joined (Berns 1990). To replicate the covalently closed terminal sequence, the termini are nicked on one of the two strands, and the newly exposed 3′ OH primer that is generated by the nick is used to repair the terminal sequence. This process is similar to the replication of the autonomous DNA viruses and ensures the integrity of the terminal sequences. The helicase activity of Rep68/Rep78 is thought to be involved in unwinding the covalently closed end of the linear viral DNA after it makes the site-specific nick at the trs site. As described above for T antigen, ATP is thought to stimulate multimerization facilitating the formation of double hexamer structures on the origin of DNA synthesis, and these double hexamers are believed to be active for helicase activity. The linear duplex end is then unwound to reform a terminal hairpin, thus providing a 3′-OH primer for strand-displacement synthesis. Elongation from the hairpin primer then generates a single-stranded genome (which is presumably packaged) and a new RF molecule, which again can undergo terminal resolution.

As with MVM, the cellular proteins involved in leading-strand DNA synthesis have also been implicated in the elongation step of AAV DNA replication including RPA, RF-C, PCNA, and a DNA polymerase (Christensen and Tattersall 2002). No requirement for DNA polymerase α-primase has been demonstrated. In an in vitro replication system, purified cellular factors PCNA, RPA, and RF-C and a partially purified fraction containing cellular DNA polymerases are necessary for reconstituting AAV DNA replication. However, investigators were unable to reconstitute activity in assays using combinations of known polymerases, suggesting that an additional cellular factor, which had not been previously identified in the SV40 system, may be necessary for AAV DNA synthesis

Requirement for helper virus In the absence of helper virus, only limited AAV genome replication can occur, and integration of the virus into a specific region of the host chromosome occurs. Interestingly, some transformed cell lines which have been treated with genotoxic agents (heat shock, hydroxyurea, UV light, or carcinogens) can support AAV DNA replication in the absence of helper virus (Yakobson et al. 1989).

Helper activity can be supplied by adenovirus and herpesviruses (including both HSV and HCMV). In the case of Ad, five genetic regions, the E1A, E1B, E4, E2A, and VA regions, are required for complete helper function (Richardson and Westphal 1981). However, none of these genes appears to be directly involved in AAV DNA replication. Genetic analyses have suggested that the role of Ad co-infection is primarily to maximize the synthesis of AAV-encoded gene products and possibly cellular genes that are required for AAV DNA replication. In the case of HSV, the minimal proteins that support AAV are the single-stranded DNA-binding proteins, ICP8 and the three components of the helicase/primase complex (UL5, UL52, and UL8) (Weindler and Heilbronn 1991). Interestingly however, the helicase and primase activities of the HSV proteins are not required for helper activity (Stracker et al. 2004). It has been suggested that the helper activity of the four proteins may be important as a scaffold which can recruit viral and cellular proteins important for AAV replication. Furthermore, it appears that the localization within the nucleus is important for efficiency of AAV replication. Both adenovirus and herpesviruses replicate at discrete sites within the nucleus and are able to subvert host cellular mechanisms to enhance viral replication (discussed below) (Carrington-Lawrence and Weller 2003; Wilkinson and Weller 2003). As discussed above, several viral replication proteins have been shown to interact directly with RPA, including T antigen and E1 of papillomaviruses. AAV rep and MVM NS1 have also been reported to interact with RPA, suggesting that recruitment of RPA and other cellular proteins may be important for parvoviral replication (Christensen and Tattersall 2002; Stenlund 2003; Stracker et al. 2004).

Summary Parvoviruses replication proteins NS1 for MVM and Rep68/78 for AAV act to nick the viral DNA and also as oligomeric helicases. Strand displacement synthesis is then carried out using cellular replication machinery; however, since only leading-strand synthesis occurs, the cellular machinery needed for lagging-strand DNA synthesis does not appear to be involved in parvovirus DNA replication.

ADENOVIRUSES

Adenoviruses cause respiratory infections and conjunctivitis among other ailments and have been isolated from a wide range of mammalian and avian hosts. Human adenoviruses can also cause morphological transformation in rodent cells. Forty-nine human adenovirus serotypes have been identified. All adenoviruses isolated to date contain a linear, double-stranded DNA genome of approximately 35 kbp packaged in a nonenveloped icosahedral capsid (Depamphilis 1996).

General features of adenoviral DNA replication

The linear genome contains two copies of the viral origin within the terminal inverted repeats. Initiation can occur at either end of the viral genome resulting in the formation of a daughter strand and the displacement of one of the parental strands (reviewed in Depamphilis 1996). The displaced parental strand can then serve as a template for the synthesis of a second daughter strand. The DNA replication strategies of this moderately sized DNA virus exhibit several unusual features. For instance, in contrast to the parvo-, polyoma-, and papillomaviruses, adenovirus encodes its own DNA polymerase (pol) and DNA-binding protein (DBP). Another interesting feature is the covalent attachment of a 55 kDa terminal protein (TP) to the 5′ end of each strand. The covalent attachment of TP results from that fact that adenovirus utilizes an unusual protein priming mechanism for replication initiation. Three cellular proteins have been shown to stimulate viral DNA synthesis: two transcription factors nuclear factor I (NF1) and Oct-1 and a topoisomerase (NF-II) (de Jong and van der Vliet 1999). Thus this virus is intermediate between the smaller DNA viruses which only encode one viral replication protein, and the larger herpes- and poxviruses which encode not only their own polymerases but most or all (in the case of pox) of the other proteins required for DNA replication. Another interesting feature exhibited by adenovirus will be discussed at the end of this chapter and relates to complex virus–host interactions related to intracellular localization and inactivation of cellular response signals.

As with the SV40 system, the identification of viral and cellular proteins involved in DNA replication was facilitated by the development of a soluble cell-free DNA-replication system. These experiments indicated that adenovirus replication requires three virally encoded proteins: precursor TP (pTP), DNA polymerase (pol) and the DBP. The availability of the reconstituted cell free replication system also allowed the identification of two cellular transcription proteins required for efficient initiation, NF1 and Oct-1 and a third cellular protein, the type I topoisomerase NFII required for efficient elongation in the strand displacement synthesis reaction.

ADENOVIRUS GENOME

The linear double-stranded DNA genome consists of five early transcription units, two delayed early units,

and one late unit. Both strands of the viral genome are transcribed although the majority of viral genes are generated from the so-called rightward reading strand. Differential spicing and the use of alternate splicing increase complexity of viral gene expression (Depamphilis 1996).

Origin of replication

The origin of the best studied adenovirus (Ad 2) consists of two distinct regions, a minimal origin region within the first 18 bp and a second region 19–51 which serves to enhance the efficiency of the initiation reaction. The minimal origin (1–18) contains a 10-bp region (bps 9–18) conserved in all adenovirus terminal regions. The minimal origin by itself can only support a limited, basal level of initiation of DNA replication. The auxiliary region contains binding sites for the cellular proteins NF1 and Oct-1. Interestingly, the ori region for another adenovirus, Ad 4, requires only the terminal 18 bp of the viral genome for efficient viral replication. Ad 4 does not seem to require the host factors NF1 and Oct-1 (de Jong and van der Vliet 1999).

Viral proteins involved in DNA synthesis

Adenoviruses encode three viral proteins that are essential for DNA synthesis, the adenovirus polymerase (Ad pol), the pTP and the single-stranded DBP (reviewed in Depamphilis 1996). Sequence analysis reveals that the 140Ad pol is related to the larger family of DNA polymerases. Within this family, the Ad pol is a member of a subfamily of protein-priming DNA polymerases. The polymerase activity of the pol protein is located at the C terminus of the protein (Brenkman et al. 2002). The Ad pol is capable of catalyzing two types of reactions: the covalent addition of dCTP to a hydroxyl residue on a serine in the 80 kDa pTP, and the elongation of a growing DNA chain from the protein primer terminus (de Jong et al. 2003b). It is believed that the switch from a protein- to a DNA-priming polymerization mode may require a conformational change within the polymerase. Biochemical analysis of Ad pol has shown that it replicates DNA in a processive manner and that it has a distributive 3′–5′ exonuclease activity on single-stranded DNA. Both the polymerase and exonuclease activities are decreased when pTP is complexed with Ad pol. This difference in activity depending on association with pTP may explain the switch from protein to DNA-priming mode in that pTP is believed to dissociate from pol before elongation proceeds (de Jong et al. 2003a). Dissociation from pTP is believed to increase processivity of pol. The viral DBP can stimulate the activity of the polymerase and can also increase its processivity.

The 72-kDa single-stranded DBP is essential for DNA replication. This was originally determined by the isolation of temperature sensitive mutations in the DBP gene. DBP participates in the initiation of DNA synthesis as well as the elongation step. DBP stimulates initiation by enhancing the binding of Pol to the origin of replication (van Breukelen et al. 2003). DBP helps to unwind the double-stranded DNA template and enhances the processivity of Pol by the removal of secondary structures. DBP binds single-stranded DNA in a sequence-independent and cooperative manner. Interestingly, DBP can support the movement of the replication fork over large distances without hydrolysis of ATP. This property of DBP abrogates the need for a helicase during DNA synthesis. In addition to its role in DNA synthesis, DBP plays a role in control of transcription, transformation, and virus assembly. The DNA-binding domain resides in the C terminal 174–529 residues. The N-terminal domain contains the nuclear localization signal.

The 671 amino-acid pTP protein makes many contacts with viral DNA and with other proteins during initiation of viral DNA synthesis. The N terminus interacts with DNA and C-terminal residues interact with Ad DNA pol (de Jong et al. 2003a). pTP also appears to harbor multiple binding sites for Oct 1. The most important single amino acid in pTP is Ser 580, which is covalently coupled to the incoming dCTP (de Jong et al. 2003a). Ad5 pTP contains three protease cleavage sites that are recognized by a virally encoded protease. Cleavage at the TP site most likely occurs after packaging into the viral particle, generating a TP-DNA complex which lacks the N-terminal 349 amino acids of pTP. Another interesting feature of the pTP is its apparent ability to attach to the nuclear matrix. This interaction could provide a scaffold for the recruitment of replication proteins that explains the observation of specific replication foci in the nucleus (see below). Thus the important attributes of pTP include multiple DNA and protein contacts, the presence of Ser 580 which becomes covalently attached to the nascent DNA chain and its ability to undergo cleavage.

Cellular proteins

Oct-1 is a human transcription factor that can stimulate both RNA pol II and pol III transcription from a variety of promoters. It consists of a central bipartite POU DNA binding domain surrounded by activation regions. POU domains can recognize a variety of different promoter DNA sequences. Although adenovirus DNA replication can occur in vitro with only the viral genome and the three virally encoded replication proteins, pTP, pol, and DBP, replication is stimulated up to 200-fold by the addition of the cellular transcription factors Oct-1 and NF1 (de Jong and van der Vliet 1999). The Oct-1 protein interacts with pTP directly and the presence of an Oct-1 binding site in the origin stimulates viral replication in vivo. Oct-1 is believed to enhance the DNA binding of pTP–pol by lowering its dissociation rate leading to a model in which Oct-1 tethers pTP–pol to the replication

origin. NF1 is another cellular transcription factor which binds as a dimer to viral and cellular promoters. A type II cellular topoisomerase, nuclear factor II, is also required for adenovirus DNA replication and it thought to relieve overwinding of the template during replication (de Jong and van der Vliet 1999).

Mechanism of viral DNA synthesis

A mechanism for initiation and elongation of viral DNA synthesis has now emerged.

Initiation The first stage of DNA replication involves the formation of a preinitiation complex comprising NF1, Oct-1, pTP, Pol, and DBP at the origin of replication. The recruitment of viral and cellular proteins to origins of replication is a theme repeated in many other viral and cellular replication systems studied. In the first step of initiation a heterodimer of pTP and pol assembles at the origin of replication in a binding reaction stimulated by the binding of cellular transcription proteins NF1 and Oct-1 to adjacent sites (see Figure 8). NF1 and Oct-1 apparently target the pTP-Pol complex to the origin (de Jong and van der Vliet 1999). The DBP can also stimulate the binding of Pol at the origin. The ability of both cellular proteins NF1 and Oct-1 and DBP to stimulate binding of pTP–pol at the origin illustrates the importance of these types of protein–protein interactions in recruitment of the components of a replication machinery to viral origins of replication.

DNA replication is initiated by an unusual protein priming mechanism in which a covalent attachment is formed between the first base and a serine residue in pTP (de Jong et al. 2003b). This reaction is catalyzed by pol, but relies on multiple DNA–protein and protein–protein interactions which act to stabilize the preinitiation complex formed at the adenovirus origin of DNA replication. The pTP and pol must assemble in such a way that the serine-580 in pTP is accessible to the Ad pol catalytic site and the DNA template to react with the first nucleotide to be added, dCTP to give dCMP, in the protein priming reaction (de Jong et al. 2003a). The addition of dCMP is template driven as DNA synthesis is initiated opposite the fourth base of the template strand. In a reaction catalyzed by the Ad polymerase, CMP is covalently bound to the hydroxyl group of a serine residue in the primer pTP. Two more nucleotides are added forming a trinucleotide intermediate (pTP–CAT). Then, in another remarkable reaction, the trinucleotide intermediate jumps back to base pair with template bases 1 to 3 (another CAT triplet). pTP then starts to dissociate from Ad pol (de Jong et al. 2003b).

Elongation and strand displacement synthesis After dissociation, pol replicates the entire adenovirus genome resulting in strand displacement DNA synthesis of the nontemplate strand. Oct-1 dissociates as the polymerase elongates past the Oct-1 binding site. Strand displacement elongation synthesis requires DBP and another cellular protein, type I topoisomerase nuclear factor II. At late times after infection, pTP is processed by a virus-encoded protease into the mature TP. The displaced strand is coated by DBP and by virtue of its inverted terminal repeats it can form a panhandle type molecule which contains a stem reminiscent of the duplex of the initial double-stranded DNA template. The duplex can then be recognized by NF1, Oct-1 and the pTP–pol heterodimer and a new cycle of protein primed DNA synthesis can occur (de Jong et al. 2003b).

Summary

In summary, adenovirus DNA replication is of interest because of its intermediate size and coding potential; it encodes many but not all DNA replication proteins. It is thus a relatively simple replication system compared to SV40 and the other smaller DNA viruses which utilizes the very elaborate cellular replication complex. The protein priming mechanism used by adenovirus and the lack of a requirement for a helicase contribute to the simplicity of this system compared to polyoma- and papillomaviruses that utilize cellular polymerases. Other DNA viruses which encode replication machinery such as the herpesviruses and poxviruses are also much more complex. Also of interest are the complex interactions between adenovirus and the host cell.

HERPESVIRUSES

The family *Herpesviridae* encompasses a wide variety of both human and animal pathogens capable of causing medically and economically important diseases in a broad range of hosts. Eight are known to infect humans including herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2), Epstein–Barr virus (EBV), cytomegalovirus (HCMV), varicella-zoster virus (VZV), human herpesvirus 6 (HHV-6), human herpesvirus 7 (HHV-7), and Kaposi's sarcoma herpesvirus (KSHV). Herpesviruses, in general, share many aspects of virion structure, genomic organization, and life cycle (described in Herpesviruses: general properties). For the purposes of this chapter, HSV-1 will be discussed as the primary example of herpesvirus DNA replication; HSV has been studied more extensively than the other herpesviruses, perhaps due to the fact that it is amenable to both genetic and biochemical analysis.

General features of DNA replication

The herpesviruses encode a large number of replication proteins, some of which are functional analogues of cellular replication machinery. Furthermore, the virus appears to have evolved a strategy of DNA replication

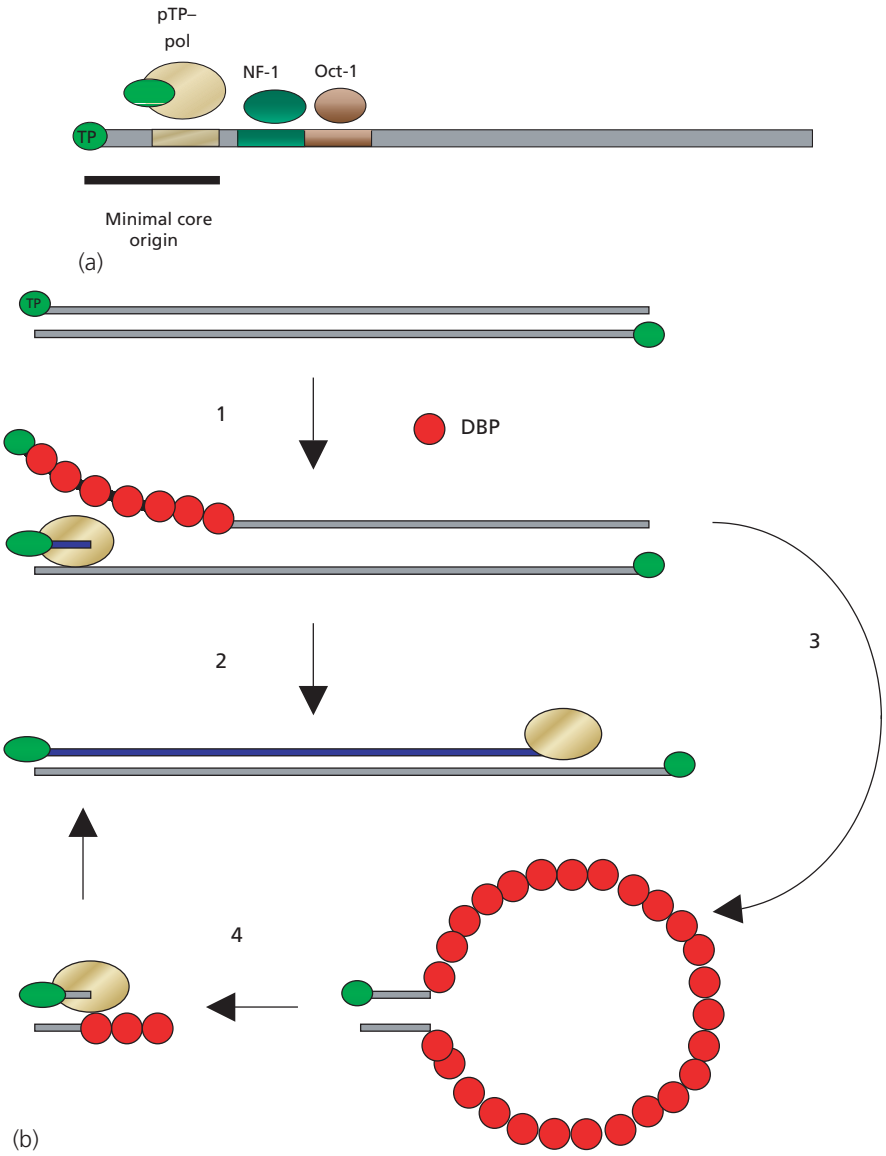

Figure 8 *Replication of adenoviral DNA.* **(a)** *The minimal core adenovirus origin of replication consists of the terminal 18 bp of the viral genome which contain the binding site for the pTP–pol heterodimer (9–18 bp). Adjacent to the 9–18 bp region are binding sites for the cellular transcriptional activators NFI (bind residues 25–39) and Oct-1 (binds 39–48), and these proteins facilitate the initiation reaction by binding at the origin and stimulating the association of the pTP–pol heterodimer to the origin. The pTP–pol interaction with the origin is stabilized by interactions with the TP–DNA, between pTP and Oct-1, and Adpol and NF1.* **(b)** *Step 1.The initiation of adenoviral DNA synthesis involves the assembly of a heterodimer consisting of the preterminal protein (pTP) and DNA polymerase (pol) (light green and gold). This heterodimer forms a preinitiation complex with the minimal core origin of replication. DNA replication is initiated by an pol-catalyzed protein priming mechanism in which a covalent bond is formed between the -phosphoryl group of the terminal residue, dCMP, and the hydroxyl group of a serine residue in pTPB. Step 2. The free 3′ OH group of the pTP–dCMP moiety primes elongation in a leading strand type reaction, resulting in the displacement of the non-template strand which becomes coated with DSB, the single-stranded binding protein. The elongation reaction also requires a cellular topoisomerase. Step 3. The displaced strand can form a panhandle reaction due to the complementarity of the inverted repeats at the termini of the adenoviral genome. The short duplex stem can be used to initiate a new round of viral DNA synthesis, steps 3 and 4. At later times in infection pTP (larger green oval) is processed by a virus-encoded protease into the mature TP (smaller green oval) (not shown).*

which utilizes DNA recombination (Wilkinson and Weller 2003). This feature is reminiscent of several of the large DNA bacteriophages including T4 and lambda. The viral genomes are linear molecules which replicate through longer-than-unit-length concatemers. Monomeric genomic units are packaged by cleavage from concatemers in a reaction that occurs in conjunction with the uptake of genomes into preassembled capsids.

HSV GENOME

The genome of HSV is large (152 kbp) and structurally complex, containing two unique regions (U_L and U_S)

that are flanked by the inverted repeat sequences *b* and *c*, respectively. The *a* sequence is present at both termini and an inverted copy is present at the U_L–U_S junction (Figure 9a). The HSV genome is capable of genomic inversions in which the U_L and U_S components invert their orientation during replication. HSV-1 is believed to encode over 80 open reading frames. Viral genes are classified as immediate–early, early or late and are transcribed from both strands of the viral genome.

Origins of DNA replication

Three origins of replication have been identified within the HSV genome (Figure 9b) (reviewed in Marintcheva and Weller 2001). One origin, OriS, is present in each 'c' component of the short region and thus is present twice in the viral genome and one origin, OriL, is present in the unique long region between the major DNA binding protein (ICP8) and the DNA polymerase. Both origins contain AT-rich sequences and several recognition sites for UL9, the origin binding protein. OriL contains a near perfect palindrome of 144 bp while OriS contains a shorter palindrome. Both origins are situated between transcriptional initiation sites. OriL, and one copy of OriS, can be deleted without affecting the ability of the virus to multiply, suggesting that viral replication can occur in genomes containing only one copy of the genome.

Viral replication proteins

The HSV-1 genome encodes seven essential replication proteins and several nonessential replication proteins (Table 5) (Challberg 1986). These include an origin

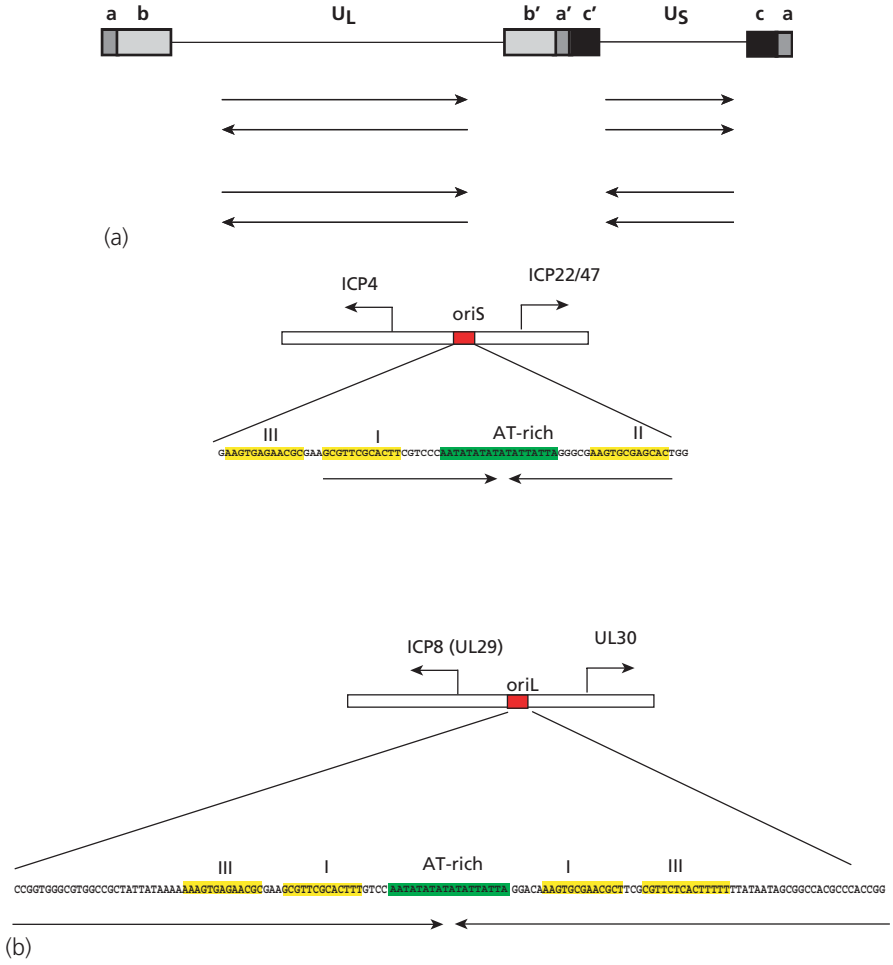

Figure 9 HSV *genome and origins of replication. A. The HSV-1 genome consists of two unique regions* U_L *and* U_S *flanked by repeated sequences.* U_L *is flanked by* ab *and* b'a'*;* *whereas,* U_S *is flanked by* ac *and* c'a'*. During infection, the two unique regions invert relative to each other. The arrows reflect possible orientations of the* U_L *and* U_S *segments as a result of genomic inversion.* **(b)** *HSV-1 Origins of replication. OriS is situated between the immediate early genes ICP4 and ICP22/47. It contains three UL9 binding sites highlighted in yellow (Boxes I, II, and III) and an AT-rich region (highlighted in green). OriS also contains an almost perfect 22-bp palindrome (marked with arrows) OriL is situated between the* ICP8 *gene (*UC29*) and the DNA polymerase gene (*UL30*). It contains four binding sites for the origin recognition protein UL9 highlighted in yellow (Boxes I, II, III, and IV), and AT-rich region (highlighted in green), and a perfect 144-bp palindrome (marked with arrows).*

Table 5 Herpes simplex virus *replication proteins*

Viral Protein	Function
UL30 (DNA pol)	Synthesis of leading- and lagging-strand DNA; associated 3′ to 5′ proofreading exonuclease; target for several antiviral drugs
UL42	HSV DNA pol processivity factor
UL9	Origin binding; DNA-stimulated ATPase and helicase
UL5, UL8, and UL52	Helicase primase complex; UL8 interacts with ICP8 and HSV pol
ICP8 (UL29)	Viral single-strand DNA-binding protein; binds cooperatively to single-stranded DNA; binds UL42 protein
Thymidine kinase	Phosphorylates thymidine; essential in nondividing cells
Ribonucleotide reductase	Reduces ribose to deoxyribose; essential in nondividing cells
dUTPase	Hydrolyzes dUTP to dUMP; prevents uracil incorporation into DNA
Uracil N glycosylase	Removes uracil from DNA; may be important for DNA repair
Alkaline nuclease (UL12)	Interacts with ICP8 and may promote single-stranded annealing during recombination-dependent DNA replication

binding protein (UL9) and six core replication proteins including a two subunit DNA polymerase (UL30 and UL42), a single-stranded DNA-binding protein (known as ICP8 or UL29) and a three subunit helicase/primase complex (UL5, UL8, and UL52) (Challberg 1986; reviewed in Marintcheva and Weller 2001). Among the eight human herpesviruses and dozens of animal herpesviruses, most encode homologues of the six core replication viral proteins involved in DNA replication, and it is likely that the strategy of replication is also conserved.

UL9

UL9 is a 94-kDa protein possessing the following activities: DNA-dependent nucleoside triphosphatase, DNA helicase on partially double-stranded substrates, ability to form dimers in solution, and cooperative origin-specific DNA binding. The ability of UL9 to bind specifically to origin DNA has been localized to the carboxy-terminal one-third (residues 564–832) of UL9. Protein sequence analysis indicates that the N-terminal domain (residues 1–534) contain seven conserved helicase motifs, characteristic of the SF2 family of helicases. The nuclear localization signal (NLS) of UL9 has been mapped to the C terminal 105 amino acid residues (reviewed in Marintcheva and Weller 2001).

UL30/UL42

UL30 encodes the 140 kDal catalytic subunit of the HSV polymerase, and UL42 encodes the 53 kDal processivity factor. Since no viral DNA synthesis can be detected in the presence of drugs which inhibit the viral polymerase or in cells infected with mutants defective for viral polymerase, it is believed that UL30/UL42 is the sole polymerase needed during viral DNA replication and that it functions as both the leading and lagging strand polymerase. The HSV polymerase has been studied extensively and is the target for antiviral drugs.

UL5/UL8/UL52

The HSV-1 helicase/primase is a three protein heterotrimer consisting of the products of the *UL5*, *UL8*, and *UL52* genes. All three genes are essential in cell culture. The *UL5*/*UL8*/*UL52* complex displays DNA-dependent ATPase, primase, and helicase activities (reviewed in Marintcheva and Weller 2001). A subcomplex consisting of UL5/UL52 displays similar activities. The precise function of UL8 within the heterotrimeric complex is not clear. In vitro, the helicase and primase activities do not depend on UL8; however, the ATPase and primase activities of the UL5/UL52 subcomplex can be stimulated in vitro by the addition of UL8. UL8 may also play a role in the proper localization of the UL5/UL8/UL52 complex to the nucleus. Furthermore, since UL8 can interact with other members of the replication machinery including UL9, UL30, and ICP8, it appears that UL8 may act to coordinate complex protein–protein interactions which occur at the replication fork. UL52 contains a motif conserved in many primases which, when altered, abolishes primase but not ATPase and helicase activity. This suggests that the UL52 subunit is likely the primase of the complex; however, recent work indicates that the UL52 subunit may contribute significantly to helicase activity as well (Carrington-Lawrence and Weller 2003). Sequence analysis indicates that UL5 contains seven motifs found in a large superfamily of known and putative helicases, SF1. Thus UL5 is likely to be the helicase of the complex, although it appears that UL52 may also be involved in helicase activity, perhaps by providing at least one DNA binding site.

UL29 or ICP8

ICP8 is the 130 kDa single-stranded binding protein of HSV. ICP8 binds preferentially to ssDNA and exhibits helix-destabilizing activity. ICP8 can also promote strand transfer and is believed to play a role in the high level of recombination exhibited during HSV DNA replication.

Recent work indicates that through its interaction with a viral nuclease (UL12), this two subunit complex may constitute a simple recombinase analogous to the simple red recombinase encoded by bacteriophage lambda (Reuven et al. 2004).

ICP8 is known to interact with other DNA replication proteins such as UL9, UL8, and HSV polymerase, and is believed to be essential for both the initiation and elongation of viral DNA synthesis. ICP8 also plays a role in the localization of viral proteins to replication compartments in infected cell nuclei and in the control of viral gene transcription.

Nonessential viral gene products

In addition to the seven required viral replication proteins, HSV also encodes several nonessential auxilary proteins such as thymidine kinase, deoxyuridine triphosphatase, ribonucleotide reductase, and uracil *N*-glycosylase. Some of these proteins participate in nucleotide biosynthesis and others such as dUTPase and uracil-*N*-glycosylase may be important in preventing misincorporation of uracil residues into the viral genome.

Overall model for HSV DNA replication

Although the exact mechanism of HSV DNA replication is not known, it has long been recognized that the products of DNA replication are larger-than-unit-length concatemers consisting of tandem repeats of the viral genome (reviewed in Marintcheva and Weller 2001). Most of the incoming viral DNA molecules lose their free ends shortly after infection by a process that does not require de novo protein synthesis, and the simplest interpretation of these results is that the viral genome loses its free ends through the formation of a covalently closed circular molecule. It was previously thought that linear virion DNA is rapidly circularized in infected cells and that concatemers were generated by rolling circle replication; however, this model has never been directly confirmed experimentally. Several aspects of this model, including the initial circularization and the rolling circle mechanism, have recently been challenged experimentally, and new models are being considered (Jackson and De Luca 2003). For instance, replicating DNA adopts a complex, possibly branched, structure which could reflect recombination intermediates. It appears that endless viral DNA does not arise as a result of simple end-to-end joining of viral termini by nonhomologous end joining, although it is possible that homologous recombination events may play a role. New models have been proposed suggesting that the viral genome adopts an endless configuration by an intra- or intermolecular homologous recombination events which occur during replication (discussed below) (Wilkinson and Weller 2003).

Initiation Viral DNA synthesis is believed to initiate at one of the three viral origins of replication. UL9 is essential for HSV DNA replication and has been shown to bind the origins of DNA replication in a cooperative and sequence-specific manner; however, many details of this reaction are still unclear. For instance, although UL9 is believed to be an ATP-dependent DNA helicase, in vitro, it has not been shown to unwind duplex DNA containing an origin of replication. Some distortion at this region can be detected but no actual unwinding (reviewed in Marintcheva and Weller 2001). This is in contrast to SV40 large T antigen that is able to unwind duplex DNA in an ATP-dependent fashion. Recent evidence suggests that UL9 binding at the origin may not be as straightforward as binding to its recognition site within duplex DNA. In in vitro experiments, single-stranded oriS has been reported to fold into a unique conformation, OriS*, which is stably bound by UL9. OriS* contains a stable hairpin formed by complementary base pairing between box I and box III in OriS (Aslani et al. 2001). It has been proposed that that UL9, in conjunction with the single-stranded DNA-binding protein ICP8, can convert OriS to its alternate conformation, OriS*, and form an OBP–OriS* complex. This model has not been tested in vivo however.

Elongation Once the origin is distorted by UL9 and ICP8, it is believed that the heterotrimeric helicase/primase complex can be recruited (Figure 10) (Marintcheva and Weller 2001). Several lines of evidence suggest the ordered assembly of viral replication proteins at the origin. Using immunofluorescence, a subassembly, or scaffold, has been identified consisting of five viral proteins: UL9, ICP8, and the helicase/primase. This scaffold can be detected as ICP8-containing foci in cells infected with wild-type HSV (Burkham et al. 2001). The recruitment of polymerase to this scaffold requires the presence of an active primase subunit (Carrington-Lawrence and Weller 2003). These results suggest that polymerase recruitment to replication foci requires primer synthesis and support the model of an ordered assembly of replication proteins at the replication fork leading to leading and lagging strand DNA synthesis.

Once elongation has begun, leading- and lagging-strand DNA synthesis would be expected to proceed until the replication apparatus either reaches the end of the linear DNA molecule or reaches a nick or gap. Since nicks and gaps have been reported to be present in the viral genome, this may occur soon after elongation has begun. It has recently been proposed that such an event could result in a fundamentally different mode of replication which utilizes a recombination strategy to continue DNA synthesis (Wilkinson and Weller 2003). The ability of replication to begin again after such an event may signal the second stage of replication which would be dependent on cellular or viral recombination

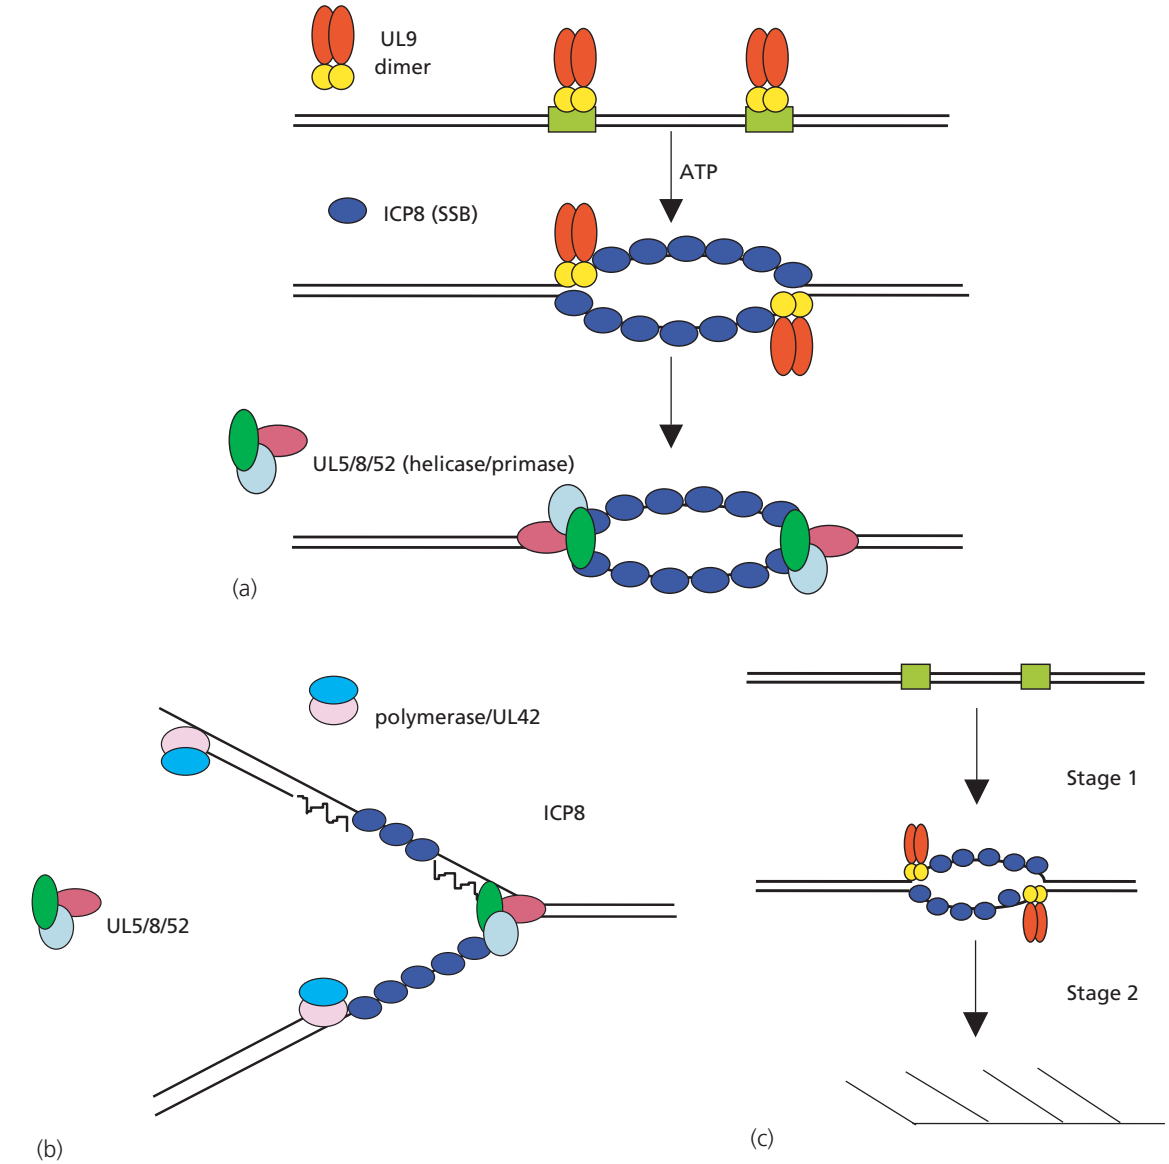

Figure 10 *Model for* HSV *DNA replication.* **(a)** *OriS can be depicted with three recognition sites for UL9, the origin-binding protein (Boxes I, II, and III) and an AT-rich linker positioned between box I and II. According to this model, UL9 dimers bind cooperatively to Boxes I and II and cause either a distortion or an opening of the AT-rich spacer region. In this step UL9 likely acts in conjunction with ICP8. Following the opening, the helicase/primase can be recruited to the complex. UL9, ICP8 and the helicase/primase complex are apparently recruited together during the formation of replication centers [80–82].* **(b)** *An HSV-1 replication fork would be expected to contain the helicase-primase complex (UL5/UL52/UL8) at the fork: UL5 would be expected to unwind duplex DNA ahead of the fork and U52 would be expected to lay down RNA primers which could then be extended by the two subunit DNA polymerase (UL30/UL42). The HSV-1 pol would also be expected to carry out leading-strand synthesis. ICP8 (UL29, SSB) would be expected to bind to ssDNA generated during HSV DNA synthesis. C). In this model, two stages of replication are envisioned, an UL9 dependent step which takes place at origins of replication (Stage 1) and a UL9 independent step which likely involves recombination-dependent replication (Stage 2).*

proteins to 'restart' the replication process. This second stage of replication would not be expected to be dependent on UL9 and, in fact, UL9 is not essential at later times after infection. The later stages of HSV replication are likely to involve recombination although it cannot be ruled out that some rolling circle replication also occurs (Figure 10c). The virus encodes a simple recombinase consisting of ICP8 and the viral nuclease UL12 (Reuven et al. 2003). It is possible that viral and cellular recombination proteins are involved during these later stages of viral DNA replication (Wilkinson and Weller 2003). Details of these reactions are the subject of on going studies.

Summary

HSV appears to be unique in the animal DNA viruses in that it exhibits a complex relationship between DNA

replication and recombination. In this respect it seems more similar to the large DNA bacteriophages, T4 and λ, which replicate via concatemers of tandemly repeated monomeric units using rolling circle replication as well as multiple pathways to carry out homologous recombination. The seven replication proteins of HSV may work in combination with both viral and cellular recombination proteins during this process, the details of which remain unclear. In summary, it appears that HSV DNA replication occurs in two stages. The first stage involves an origin-UL9 dependent step and in the second stage DNA replication may proceed in an origin-independent manner via a recombination-driven and/or rolling circle mechanism (Wilkinson and Weller 2003).

POXVIRUSES

The poxviruses make up a particularly interesting group of pathogens responsible for devastating human diseases such as smallpox. Poxviruses have been isolated from many animal hosts, and cowpox and vaccinia viruses have been used as vaccines to protect humans from the smallpox virus, variola virus. Poxviruses are unique among the DNA viruses in their ability to replicate entirely within the cytoplasm. They are large complex viruses which exhibit considerable independence from the host cells (Depamphilis 1996).

General features of poxvirus DNA replication

Poxviruses have the largest genomes of any known DNA viruses, and they have been shown to encode all of the proteins needed for DNA replication including DNA polymerase, a processivity factor, two protein kinases, a protein phosphatase, and a DNA ligase (Boyle and Traktman 2004). Although the function of the kinases and phosphatase are not entirely clear, their existence suggests that protein phosphorylation may play an important role in regulating either DNA replication or another step in the virus life cycle. DNA replication occurs in the cytoplasm in specialized foci called viral factories. After fusion of viral and cellular membranes, the inner viral core is localized in the cytoplasm, and early gene expression occurs within these cores. Early mRNAs are extruded from the core where they are translated by host ribosomes. Some of these early proteins encode replication proteins. A secondary uncoating event occurs and viral genomes are released and accessible to replication proteins. Replication occurs in two stages: synthesis of genomes as concatemeric intermediates and resolution of these concaters into mature, monomeric genomes (Depamphilis 1996).

POXVIRUS GENOMES

Poxviruses have linear double-stranded DNA genomes which vary in size from 130 kbp to around 230 kbp. The vaccinia genome has a very unusual structure: it is composed of a linear duplex of 192 kbp with covalently closed hairpin termini resembling telomeres. The genomes are AT-rich and the inverted terminal hairpin repeats also contain primarily A and T residues (Du and Traktman 1996).

Origins of replication

The termini are believed to contain the origins of replication. In vaccinia, for instance, the telomeric 65 nucleotides can be replicated in infected cells; however, the efficiency of replication increased with the inclusion of additional adjacent sequences. Maximal efficiency was obtained with plasmids containing the 200 terminal bp (Du and Traktman 1996). This region contains the hairpin loop, a region of unique sequences containing a sequence required for genome resolution and a set of 70-bp repeats. The hairpin loop contains 40 base-paired residues and a four-nucleotide loop at the very terminus. In addition, there are some unpaired residues termed extrahelical bases which are asymmetrically located; one strand has ten and the other two. This unusual genomic structure is conserved in all poxviruses. Two isoforms of the genome are found which represent inverted complements of each other and are called flip and flop. The presence of these extrahelical bases and their position within the termini are believed to be important during genome replication.

Viral proteins involved in DNA replication

Several viral proteins have been implicated in viral DNA replication; however, their roles are not well understood (Table 6). Genetic analysis has revealed three gene products, E9, D5, and B1 as important since mutants with defects in these genes are defective in DNA synthesis. Another gene, *D4*, may also be important. Some genes have been identified by sequence analysis. The *E9* gene encodes the viral DNA polymerase which is related to alpha family of DNA polymerases. This protein exhibits DNA polymerase as well as 3′ to 5′ exonuclease activity. A factor which enhances the processivity of the polymerase has been inferred by the observation that infected cell extracts contain a polymerase activity which is highly processive while the purified *E9* gene product is distributive. The product of the A20 open reading frame has been reported to be the polymerase processivity factor (Ishii and Moss 2001; Klemperer et al. 2001). Vaccinia also encodes an NTPase (*D5* gene) and a protein kinase (*B1* gene) whose precise roles in DNA replication are not clear. An early protein H5 appears to be a substrate for the B1 kinase and these two proteins interact with each other, but its role is unclear. Recent evidence suggests that A20 may interact with three other vaccinia proteins, D4, D5, and H5, and that A20 may play an important role in

Table 6 *Poxviral proteins that participate in genome replication*

Vaccinia Viral Protein	Function	Expression
DNA polymerase (E9)	Synthesis of viral DNA; associated 3′–5′ exonuclease for proofreading	Early
A20	Processivity factor	Early
D5	NTPase	Early
B1	Serine–threonine kinase	Early
D4	Uracil DNA glycosylase	Early
A50	DNA ligase	Early
Type I topoisomerase (H6)	Unknown but essential	Late (in capsid)
Thymidine kinase ((J2)	Phosphorylates thymidine; essential	Early
Thymidylate kinase (A48)	Phosphorylates TMP	Early
Ribonucleotide Reductase (F4, 14)	Reduces ribose in ribonucleotides to deoxyribose; essential in nondividing cells	Early
dUTPase (F2)	Hydrolyzes dUTP to dUMP	Early
DNase (?)	Has nicking; joining activity	Early

forming or stabilizing the DNA replication complex. Other viral proteins include a DNA ligase which is not essential in tissue culture, and enzymes involved in nucleotide biosynthesis including thymidine kinase, thymidylate kinase, and ribonucleotide reductase. The virus also encodes a Topisomerase I which is found in viral capsids and a dUTPase and a uracil DNA glycosylase which may play roles in DNA replication and/or DNA repair (De Silva and Moss 2003). Details about the precise roles of these proteins are unclear.

Mechanism of DNA replication

Although poxvirus DNA replication is not well understood, models have been suggested based on current evidence. The first step in genome replication is believed to be the introduction of a nick in sequence within the genomic terminus generating a 3′ OH which can be extended by the viral DNA polymerase. Strand displacement synthesis would be expected to extend the template to the terminus. Since the terminus itself is self complementary, a duplex hairpin can form providing a 3′ OH group that can be extended back in the other direction resulting in the formation of a dimeric tail-to-tail concatemer. This process could occur again resulting in the generation of tetrameric or even higher order concatemers. Concatemeric intermediates have been detected experimentally. This model is consistent with leading strand DNA synthesis. As with the herpesviruses, recombination is also a frequent event during poxvirus DNA replication, and it is possible that recombination events such as strand invasion may play a role in viral DNA replication.

It is believed that concatemeric intermediates can be resolved into monomeric units prior to packaging. Plasmids containing the unique resolution sequences can be resolved into linear minichromosomes with authentic hairpin termini after transfection into infected cells. The protein(s) which recognize the resolution sequences has not been identified to date.

Summary

The poxviruses provide a fascinating example of a viral DNA replication system which encodes all of the required proteins. This virus poses unique challenges experimentally which have slowed progress in elucidation of the precise roles of the viral factors.

HOST–VIRUS INTERACTIONS

In recent years it has become clear that viruses rely on the host in previously unknown ways both in terms of localization within the host cell and the utilization of host factors. For instance, viral genomes have been shown to localize to specific sites within the nucleus (Ishov and Maul 1996; Tang et al. 2000). This localization is thought to involve specific interactions with cellular proteins. In addition, several viruses exhibit complex interactions with the cell cycle. Infection with SV40 and papillomaviruses can alter the host-cell cycle by inducing the host-cell DNA synthetic machinery (Munger et al. 1989; Cheng et al. 1995). Since these viruses depend on cellular proteins such as DNA polymerases, RPA, PCNA etc., the induction of the S phase of the cell cycle is essential for genome replication. Other types of interactions involve both the utilization of host cell proteins which benefit their reproductive strategies and in some cases inactivation of cellular response mechanisms which are inhibitory.

Interactions between viral and cellular proteins

Although adeno- and herpesviruses encode their own polymerases and are therefore somewhat more indepen-

dent of the cell machinery than are the polyoma- and papillomaviruses, these viruses also exhibit very complex interactions with host cell machinery. For instance it has recently been shown that in cells infected with adenovirus, a multiprotein complex consisting of Mre11, Rad50, and NBS1 appears to be inactivated (Stracker et al. 2002). The Mre11 complex is important for double-strand break repair, and infection with adenovirus alters its activity by two mechanisms: spatial reorganization of this complex within the cell and degradation of certain components of this complex. Mutants of adenovirus which fail to inactivate the Mre11 complex have been shown to form concatemers and to replicate inefficiently (Stracker et al. 2002). The evolution of a strategy to promote replication of monomer length molecules by strand displacement as seen in Figure 8b belies a complex viral–host interaction in which some cellular pathways remain intact and others are inactivated. Recent work with herpes simplex viruses suggests that this virus inactivates a different cellular pathway, the nonhomologous end joining (NHEJ) pathway (Jackson and DeLuca 2003; Wilkinson and Weller 2003). During the earliest stages of infection, the NHEJ pathway is inactivated by spatial reorganization and by degradation. Another fascinating aspect of virus–host interactions involves the regulation of viral proteins by post-translational modification. We have seen several examples of viral proteins regulated by phosphorylation using viral and cellular protein kinases (Fanning and Knippers 1992; Nuesch et al. 2001; Ott et al. 2002). Also of interest is the use of molecular chaperones during the viral life cycle. The use of both host-encoded chaperones and virus-specific chaperones has been reported. For instance, it has been shown that in human papillomavirus, E1 protein binding to the origin can be stimulated by the human Hsp70 and Hsp40 chaperone proteins (Lin et al. 2002). Furthermore, SV40 T antigen itself is a functional molecular chaperone J protein. It is expected that chaperones will be implicated in the assembly and function of the replication machinery of many if not all DNA viruses.

Replication within replication compartments or replication centers

Viral DNA replication often takes place within well-defined regions of the cells. In the case of poxviruses, replication occurs within cytoplasmic viral factories. All other DNA viruses replicate in the nucleus, again within well defined regions. In the case of adenovirus and herpesviruses, DNA replication occurs within replication compartments or centers which contain viral genomes and viral and cellular replication proteins. The formation of such compartments may be important for replication efficiency as cellular and viral factors can be concentrated at these sites. Sequestration in such

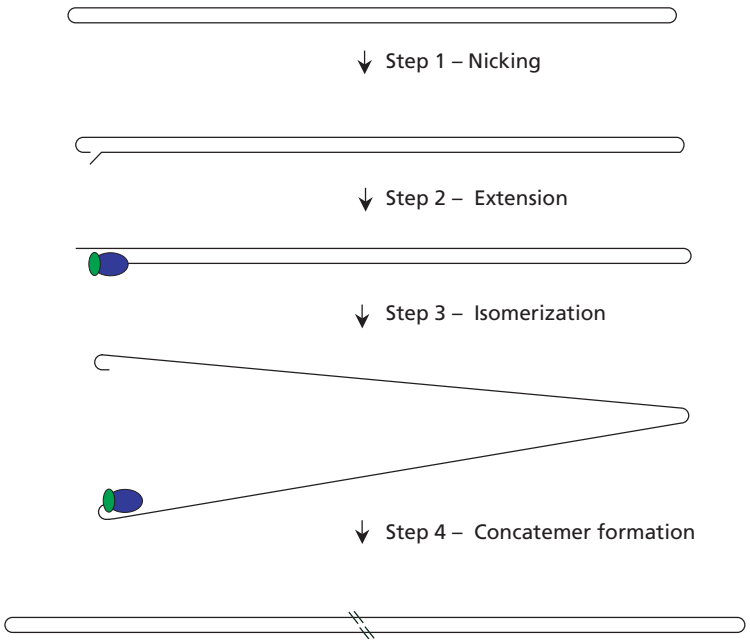

Figure 11 *Poxvirus DNA replication. A model for poxviral DNA replication is shown. The parental genome is a linear duplex with covalently closed termini. Step 1. A nick is introduced into the duplex creating a 3′ OH group which can be extended by the viral DNA polymerase and processivity factor (shown as ovals). Step 2. Replication proceeds by extension of the primer and copies the left end of the genome. Step 3. Because of the terminal redundancy, the nascent DNA can isomerize to form another hairpin. Step 4. The hairpin structure can be elongated along the length of the genome, around the hairpin and along the complementary strand to form a dimer intermediate.*

compartments may also represent a strategy for limiting access to viral genomes during replication for the purpose of inhibiting apoptosis.

Genomes of several DNA viruses which replicate in the nucleus including SV40, adenoviruses, and herpesviruses (at least HSV and HCMV) appear to localize at sites adjacent to ND10 (Ishov and Maul 1996; Tang et al. 2000; Everett 2001). ND10 are subcellular structures or foci which are defined by those which have been identified including PML containing foci known as ND10 or PML nuclear bodies or PML oncogenic domains (PODs) (Burkham et al. 2001). Viral gene expression is also believed to occur at these sites. ND10 are defined by the accumulation of PM, SP100, SUMO, and other cellular proteins involved in growth control, gene expression, and possibly DNA recombination. ND10 are dynamic structures with many of its constituents able to shuttle between the cytoplasm and the nucleus. The common association of viral DNA genomes with ND10 may indicate that proximity to ND10 or some cellular site associated with ND10 may provide a beneficial environment for viral gene expression and viral DNA replication. Cellular proteins involved in DNA recombination and repair have been shown to localize to ND10 or to ND10-related sites. Ionizing radiation induces the increased expression of PML and the relocalization of ND10 proteins to sites of DNA damage as defined by staining for γH2AX, a marker for dsDNA breaks. The relationship of DNA viruses with the repair/recombination machinery of the cell may be important for viral DNA replication (Wilkinson and Weller 2003). Viral DNA molecules which are located at or near ND10 may have access to cellular recombination and repair proteins. This may confer an advantage for DNA replication.

Viral replication proteins and cellular transformation

Several DNA viruses have been associated with human cancers and morphological transformation. The best studied is SV40 which is known to transform rodent cells in culture. SV40 large T antigen is known to deregulate cellular proliferation pathways and can efficiently immortalize primary rodent cells and transform established rodent cell lines to tumorigenicity (Simmons 2000). The transformation ability of T antigen is caused by its specific interactions with host-cell proteins. The tumor suppressor protein p53 was originally identified by its ability to interact with SV40 large T antigen. T antigen also interacts with another tumor suppressor protein, pRB, and the study of these interactions has greatly improved our understanding of the roles of these cellular proteins in the cell cycle and the role of viral oncogenes transformation. As mentioned above, the N terminus of T antigen has also been shown to contain a DnaJ domain which is required for efficient viral replication and perhaps for transformation as well. Recently, the N terminus of T antigen has also been shown to interact with the mitotic spindle checkpoint protein Bub1. Perturbations of this spindle checkpoint may result in aneuploidy and genetic instability leading to cell transformation. Thus viral proteins such as large T antigen continue to provide many insights into the host cell and to responses which lead to oncogenesis and cancer (Munger et al. 1989; Cheng et al. 1995; Simmons 2000; Longworth and Laimins 2004).

SUMMARY

The study of viral DNA replication has been important for many reasons. Replication proteins are still the major targets for antiviral therapy, and thus a thorough understanding of viral replication proteins continues to facilitate the development of novel antiviral strategies. In addition, viruses provide useful windows into the cell: most of what is currently known about mammalian DNA replication strategies came about through studies with SV40. The diversity of strategies exhibited by DNA viruses from SV40 and polyomaviruses which rely almost entirely on host-cell machinery to the poxviruses which encode all the proteins required for genome replication have provided a rich field of study. By comparing viral systems, several important principles have emerged and common mechanisms have been identified. Most viral systems require an origin recognition protein, one or more DNA polymerases, proteins that enhance processive DNA synthesis, origin unwinding and helicase functions and a mechanism for priming DNA synthesis. The diversity in priming is perhaps the most interesting: some viruses use RNA primers and discontinuous synthesis of lagging strands reminiscent of cellular DNA replication strategies, whereas others use protein priming or DNA sequence primers. Each mechanism has implications for how ends are replicated and how progeny genomes are produced during encapsidation. Adenovirus genomes replicate and are packaged primarily as monomers, while the herpesviruses replicate as concatemers which must be processed into monomers during encapsidation.

Because viruses need to replicate many copies of their genomes in relatively short periods of time, most DNA viruses have evolved very efficient replication strategies. The evolution of viral replication proteins which can recruit cellular factors results in the concentration of viral and cellular proteins in specialized regions of the cell leading to enhanced replication efficiency. It is anticipated that better understanding of the complex virus–host interactions leading to efficient viral replication will provide additional insights into eukaryotic cell biology as well. Furthermore, the ability of some viruses to transform cells suggests that important lessons of cellular transformation will be learned from the

continued study of the replication strategies of DNA viruses.

GENETIC SYSTEMS

The major aim of virus genetics is elucidation of the detailed structure of the genomes of the various types of viruses found in nature and the extent to which the individual components of the virus genome determine the biological and disease-producing potential of viruses. Virus genetics is also concerned with understanding the pattern and origin of the variability of viruses, in terms both of virus evolution and of the temporal changes in antigenicity and pathogenicity of viruses that determine the prevalence and course of virus-associated infectious diseases of humans and animals. Although virus genetics impinges on all aspects of virology, this account will be limited predominantly to a consideration of genome strategy, methods of genetic analysis, and some of the applications of genetic methodology.

Viruses display a diversity of genetic systems unparalleled in any other group of organisms. The viruses considered in this chapter are those that infect humans and higher animals. The genetic systems described here do not include all the known categories, and only occasional reference is made to viruses that infect invertebrates, plants, fungi, protozoa, algae, mycoplasmae, bacteria, and archaea (see The classification of vertebrate viruses). With the determination of the complete sequences of the genomes of many plant and animal viruses, previously unsuspected phylogenetic relationships are being revealed. For example, cowpea mosaic virus, a plant comovirus with a bipartite positive-sense RNA genome, shows organizational similarity and local sequence homology with the monopartite vertebrate picornaviruses. Tobacco mosaic virus, a monopartite positive-sense RNA virus, and alfalfa mosaic virus and brome mosaic virus, both tripartite genome viruses, show sequence relationships with the animal alphaviruses. On the basis of genome organization and comparison of RNA-dependent RNA polymerase sequences, most plant positive-sense RNA viruses can be classified into two supergroups comprising the picornavirus-like plant viruses (como-, nepo-, and potyviruses), and the *Alphavirus*-like plant viruses (tobamo-, bromo-, carla-, clostero-, cucumo-, furo-, gordei-, ilar-, potex-, tymo-, and tobraviruses) (Koonin and Dolja 1993). The picornavirus-like plant viruses and the animal picornaviruses resemble each other in encoding a number of nonstructural proteins that exhibit similar functions and show some degree of amino acid homology. The *Alphavirus*-like plant viruses are more diverse, but again they encode genes in the same relative order that specify proteins exhibiting significant sequence homology to the three nonstructural proteins of the vertebrate Sindbis virus. There is also an apparent genetic link between the potyviruses of plants and the flaviviruses of animals, in that the putative helicase protein of potyviruses exhibits a closer resemblance to the NS3 protein of flaviviruses, which contains a nucleotide-binding motif, than to the helicases of picornaviruses (Goldbach and de Haan 1993).

Although most viruses are restricted in their host range, several groups of viruses are characteristically less restricted by taxonomic barriers and may multiply in hosts of quite different origin. Some of the arthropod-borne bunyaviruses and rhabdoviruses that infect vertebrates or plants are also able to multiply in their invertebrate vector. Despite the apparent phylogenetic relationships described above, however, no contemporary virus exists that is able to multiply in both vertebrates and plants. Nonetheless, it has been demonstrated experimentally that yeast cells infected artificially can support the replication of vertebrate papillomavirus genomes (Angeletti et al. 2002), and that replication-competent chimeras of plant and animal viruses can be constructed that replicate efficiently in plant protoplasts (Peng et al. 2002).

MOLECULAR PHYLOGENY AND VIRUS EVOLUTION

The existence of plant and animal RNA viruses with similarly ordered genomes encoding proteins with similar amino acid sequences suggests a common ancestry. However, the common ancestors from which these viruses diverged probably appeared subsequent to the separation of the plant and animal kingdoms some 10^9 years ago, and divergent evolution alone cannot account for certain features of these relationships. The coupling of common genes to unique genes in several of these genomes suggests a polyphyletic origin mediated by recombination. Many viral genomes can best be regarded as different assemblages of modules of conserved genes that have arisen by a process of modular evolution. From a phylogenetic analysis of the vertebrate circoviruses and the nanoviruses of plants, both of which have small single-stranded circular DNA genomes, Gibbs and Weiller (1999) concluded that these viruses had not arisen by parallel evolution. Rather, the vertebrate circoviruses had evolved from the plant nanoviruses by a complex recombinational event which involved the incorporation of a gene from an RNA virus, possibly a vertebrate calicivirus, into a plant nanovirus DNA genome. Their hypothesis requires that the circoviruses evolved as a consequence of a host-switch whereby a nanovirus genomic DNA was transferred from a plant to a vertebrate host, perhaps as a consequence of exposure of a vertebrate to infected plant sap or via a vector. The replication-competent DNA persisted, and by a subsequent recombinational event became a virus capable of infecting vertebrate hosts. Because caliciviruses are vertebrate viruses, the hypothesis requires that the host-switch preceded the recombinational event. Unlikely as this scenario may seem, involving the hybridization of a DNA and an RNA virus, there is the precedent of Thogoto virus a negative-sense RNA virus that possess a glycoprotein gene resembling that of a DNA baculovirus (Morse et al. 1992).

The application of molecular phylogeny analysis to the large and complex DNA-containing herpesviruses has confirmed the ancient origin of these viruses and provided a timescale for their evolution. The branching pattern of the three subfamilies of the mammalian herpesviruses is congruent with that of their corresponding host lineages (McGeoch et al. 1995). Assuming a constant molecular clock, the *Alphaherpesvirinae*, *Betaherpesvirinae* and *Gammaherpesvirinae* subfamilies would have diverged $1.8–2.2 \times 10^8$ years ago, at about the time of emergence of mammals from mammal-like reptiles, and the major sublineages within these subfamilies probably arose before the radiation of placental mammals some $6–8 \times 10^7$ years ago. Paleontological dating of host lineages has suggested that the contemporary virus lineages within the subfamily *Alphaherpesvirinae* have evolved by a process of co-speciation of viruses with their mammalian hosts (McGeoch and Cook 1994). However, several avian herpesviruses are included in the *Alphaherpesvirinae* and, on the basis of similar assumptions, would have evolved independently with their avian hosts for some 80–120 million years (McGeoch and Davison 1999). Such a timescale, however, would place the origin of the avian viruses in too recent an era, as the ancestors of birds and mammals are considered to have diverged some 310 million years ago. This suggests that the avian herpesviruses may not have evolved with their hosts, but may have resulted from ancient cross-species transmissions of ancestral mammalian alphaherpesviruses to birds (McGeoch et al. 2000). Recently two other major herpesvirus lineages have been identified, one embracing fish and amphibian herpesviruses, and the other represented by unique herpesviruses recovered from bivalve molluscs. If these viruses similarly evolved with their hosts, the fish herpesviruses lineage would have been established some 450 million years ago and the invertebrate herpesvirus lineage perhaps a billion years ago. In contrast to the relationships evident between herpesviruses within the same lineage, there is no obvious relationship between herpesviruses belonging to the three different lineages (avian/mammalian, fish/amphibian, and invertebrate) in terms of amino-acid sequence comparisons, other than those functions that are common to all organisms (e.g. DNA polymerase, helicase, and primase). This extreme divergence perhaps suggests that other mechanisms of herpesvirus evolution remain to be identified. A shared ancestral root for all herpesviruses cannot be assumed, because none of the genes common to these three lineages of herpesviruses are confined to herpesviruses, and could have been acquired independently by gene capture rather than by lineal descent (Davison 2002). On the other hand, a member of the fish/amphibian lineage, Channel catfish virus, possesses a gene distantly related to the ATPase subunit of bacteriophage T4

terminase, a complex of proteins responsible for energy-dependent packaging of nascent genomes into preformed capsid. Although this gene may owe its origin to horizontal exchange, it is possible that herpesviruses share their origins with the ancestors of bacteriophage T4 and other icosahedral double-stranded DNA bacterial viruses (Davison 2002).

The ancestral origins of most other viruses cannot be deduced with any certainty from phylogenetic analysis where there is no linkage to the geological record. Generally there are few virus isolates originating from more than a few decades before the present, and even the direction of evolution cannot be discerned in all cases with any degree of certainty. The antiquity of the retroviruses, however, has been established using polymerase chain reaction methodology to screen for the presence of endogenous retroviruses in a wide range of vertebrate hosts, including amphibian, avian, mammalian, piscine, and reptilian. Phylogenetic analyses have demonstrated that viruses resembling (but not necessarily related to) two (the spumaviruses and the murine leukemialike viruses) of the seven recognized genera of retroviruses are widespread and abundant in vertebrate (but not invertebrate) genomes, whereas viruses resembling the other five genera of retroviruses are restricted to mammals and birds (Herniou et al. 1998). Calculation of the integration dates of some of the numerous families of defective human endogenous retroviruses (HERV) identified recently indicates that most of them are likely to have been part of the human lineage since it diverged from that of the Old World monkeys more than 25 million years ago (Tristem 2000). HERVs probably represent the footprints of ancient germline retroviral infections. Furthermore, HERVs may influence genome regulation through expression of retroviral genes, via genomic rearrangements and the involvement of HERV LTRs in the regulation of gene expression (Sverdlov 2000). Analysis of the human genome has revealed that some 45 percent of it consists of various types of transposable elements, with around 8 percent of human DNA derived from retrovirus-like elements (Paces et al. 2002).

THE STRATEGY OF THE VIRUS GENOME

The 'strategy of the virus genome' is a phrase that has been used to describe collectively the organization and function of the genetic information content of viruses. The mammalian viruses fall into three major categories: the DNA-containing viruses, the RNA and DNA reverse-transcribing viruses, and the RNA-containing viruses (Table 1). The DNA viruses range from viruses with small genomes, such as the parvoviruses and the papovaviruses, which depend on host-cell functions for their replication, to large genome viruses such as the nuclear herpesviruses and the cytoplasmic poxviruses, which have acquired a battery of additional genes that function to mediate replication independently of the host cell and to subvert the immune response of the host. The encoding of genetic information in RNA is unique to viruses (animal, plant, and bacterial), and RNA is the predominant molecular form of the genome in animal and plant viruses. The genomes of more than 90 percent of plant viruses consist of single- or double-stranded RNA. The reverse-transcribing viruses alternate between RNA and DNA forms of the genome; in the retroviruses the genome exists as proviral DNA integrated into the host cell genome and as RNA in the extracellular virion. By contrast, in the DNA-containing hepadnaviruses and the plant caulimoviruses (sometimes referred to as pararetroviruses) the DNA form is present as partially or completely double-stranded DNA in the virion, and the RNA form acts as a replicative intermediate in the infected cell. Exceptionally, recent evidence suggests that the replicative cycle of the foamy viruses (members of the genus *Spumavirus*, one of the seven genera of the family *Retroviridae*) resembles that of pararetroviruses in that the extracellular particles contain full-length double-stranded infectious DNA, as well as RNA (Yu et al. 1999). The spumaviruses differ from hepadnaviruses, however, in that they encode proteases and integrases, and integration is an obligate event in the viral replicative cycle.

The coding potential of viruses

The molecular sizes of the genomes of the vertebrate DNA viruses extend from the 1.7 kb of the circular single-stranded genome of porcine circovirus to the 300 kbp genome of fowlpox virus. (The genomes of the some invertebrate iridoviruses and entomopoxviruses are larger and may extend up to 383 kbp.) In contrast, the RNA viruses are more uniform, varying within a 15-fold range from the 1.7 kb of the single-stranded helper-dependent deltavirus to the 31 kb of certain coronaviruses. This circumstance has been interpreted as a reflection of the low fidelity of viral RNA polymerases, which lack proofreading capability. The consequent high mutability of RNA viruses may impose an upper limit on the size of informational RNA molecules.

Table 1 lists the currently recognized vertebrate viruses according to the taxonomy defined in the Seventh Report of the International Committee on Taxonomy of Viruses (ICTV) (Van Regenmortel et al. 2000; see also The classification of vertebrate viruses). The first column lists viruses by family, and the second column gives an indication of the inherent diversity of the group in terms of the number of distinct genera and their constituent species, as currently listed by the individual specialist study groups of the ICTV. This is of course an imperfect measure of genetic diversity, as the extent of knowledge of any particular

Table 1 *The properties of the vertebrate virus genome*

Family		Diversity								
(Order)	Subfamily (unassigned genus)	Genera	Species	Nucleic acid type	Strandedness sense	Configuration	Size	ORF	Particle type	Other features
The DNA viruses										
Parvoviridae		3 (+3 invert)	34 (+5 invert)	DNA	Single (negative or positive)	Linear	4.7–5 kb	2 major	isometric	Nuclear mitosis dependent
Circoviridae		2	4	DNA	Single (negative or ambisense)	Circular	1.8–3.8 kb	3 major (overlaps)	isometric	Nuclear S phase dependent
	(*Anellovirus*)	1	4	DNA	Single (negative)	Circular	2.9–3.8 kb	2 major (overlap)	isometric	High genetic heterogeneity
Papovaviridae		1	12	DNA	Double	Circular	5.2 kb	8 (overlaps)	isometric	Early and late mRNA ex opp. strands
Papillomaviridae		1	7	DNA	Double	Circular	6.8–8.4 kb	9 or 10 (overlaps)	isometric	Early and late mRNA ex same strand
Iridoviridae		1 (+3 invert)	1 (+4 invert)	DNA	Double	Circular (circularly permuted)	150–170 kbp (107 kbp unit)	>40	isometric (enveloped)	Nongenetic Reactivation
Adenoviridae		2	30	DNA	Double	Linear	26–45 kbp	40 (splicing)	Isometric (fibers at vertices)	Covalent-linked protein temporaral gene exp.
Herpesviridae										
	Alphaherpesvirinae	4	23	DNA	Double	Complex linear 4 isomers in HSV	*ca*. 150 kbp	70–100 splicing rare	isometric	Latency in sensory ganglia
	Betaherpesvirinae	3	7	DNA	Double	Linear	*ca*. 235 kbp	*ca*. 200 splicing common	isometric	Latency in lymphoreticular cells
	Gammaherpesvirinae	2	20	DNA	Double	Linear	*ca*. 170 kbp	*ca*. 150 splicing common	isometric	Latency in B lymphocytes
	(Ictalurid herpes-like viruses)		1	DNA	Double	Linear	134 kbp	*ca*. 80	isometric	Phylogeny uncertain
Asfarviridae		1	1	DNA (inverted term rep.)	Double	Linear, Covalently closed	170–190 kbp	*ca*. 150	Complex (NC/isometric/env.)	Perinuclear factories nucleus dependent
Poxviridae										
	Chordopoxvirinae (+1 invert subfamily)	8 (3 invert.)	35 (27 invert.)	DNA (cytoplasmic)	Double	Linear, Covalently closed	130–250 kbp	*ca*. 150–300	complex	Inclusions temporaral expression

Filoviridae (O. Mononegavirales)		2	5	RNA	Single (negative sense)	Linear	19 kb	7 (overlaps)	bacilliform/env.	Recomb. deficient GP may be edited
Arenaviridae		1	19	RNA	Single (ambisense)	Linear ×2 (L and S segments)	L – 7.5 kb S – 3.5 kb	4	pleomorphic/env.	Rodent-borne Subunit reassortment
Bunyaviridae		4 (and 1 plant)	87 (and 8 plant)	RNA	Single (negative and ambisense)	Linear ×3, (L, M, and S segments)	L - 6/12 kb M - 3/5 kb S - 1/1.7 kb	6 (overlaps)	spherical/enveloped	Most arboviruses Subunit reassortment
Orthomyxoviridae		5	6	RNA	Single (negative sense)	Linear ×6, 7 or 8 (n = 900– 2350 kb)	10–14.6 kb (total)	10 (spl/op)	spherical/enveloped	Nuclear phase subunit reassortment
Birnaviridae		2 (+1 invert.)	3 (+1 invert.)	RNA	Double	Linear (n = 2715– 3104 kbp)	6 kbp (total)	5 (overlap)	Isometric (single shell)	Subunit reassortment
Reoviridae		5 (+4 pl/inv)	38 (+27 pl/inv)	RNA	Double	Linear 11, or 12 (three size classes)	19–32 kbp (total)	10+ (overlaps)	Isometic (1, 2, or 3 shells)	Subunit reassortment

env. enveloped; exp. expression; invert, invertebrates; opp, opposite; pl/inv, plant and invertebrate; PTC, post-translational cleavage; recomb. recombination; sgRNA, subgenomic RNA; str. structural; term rep, terminal repeat.

taxonomic group is determined to some degree by the extent of its adverse interactions with human and animal populations.

Vertebrate virus genomes, according to virus family, may be linear or circular, single-, or double-stranded, covalently linked to small terminal proteins, or may exist as a unique complement of subunits. The minimum information content of a viral genome can be estimated from the number of nonoverlapping coding triplets if the complete nucleotide sequence is known, or if not, from the ratio of the molecular mass of the genome and the gene products. As a rough estimate the ratio of the molecular mass of genome and gene products is approximately 10:1 for single-stranded genomes and 20:1 for double-stranded genome viruses. Thus, for example, the 4.2×10^6 Mr of the genome of the rhabdovirus vesicular stomatitis Indiana virus (VSIV) is sufficient to code for polypeptides with a total mass of 400 kDa, which approximates closely to the actual 396 kDa of the five gene products of VSV. This is an extreme case, however, because in the genome of this virus the noncoding regions are limited to dinucleotide intergenic junctions, and short leader and trailer regions.

The relationship between linear length and coding capacity is maintained in the larger DNA viruses, but the coding capacity of smaller virus genomes can be considerably expanded by a number of devices operating at the levels of genome organization, mRNA transcription and translation strategies. At the level of genome organization these devices can include overlapping reading frames (almost ubiquitous), and transcription from both DNA strands (*Polyomavirus*); at the level of transcription, mRNA splicing (most nuclear viruses), the generation of mRNA families by alternate splicing (adenoviruses), accessing of multiple open reading frames by RNA editing (paramyxoviruses), use of alternate start sites (adenoviruses and paramyxoviruses) and alternate termination sites (paramyxoviruses and rhabdoviruses), and nontemplated insertion of nucleotides (paramyxoviruses); and at the level of translation, leaky scanning of mRNA (paramyxovvirus *P* gene products), suppression of termination (retrovirus *gag–pol*), ribosomal frameshifting, (several viruses), posttranslational cleavage of polyprotein precursors (picornaviruses, togaviruses, and retroviruses), the presence of internal ribosome entry sites (picornaviruses and flaviviruses), usurpation of host factors (several viruses), and transactivation of host genes (lentiviruses).

Ribosomal frameshifting is observed predominantly in RNA viruses and is often involved in the expression of replicases (Brierle 1995). Slippage of ribosomes into the –1 reading frame (in a 5′ direction) occurs at a specific site comprising two essential elements: a homopolymeric slippage sequence separated by five to eight bases from an RNA pseudoknot structure. Ribosomal frameshifting may be a strategy to achieve stoichiometry of gene products or to ensure inclusion of replicative enzymes in virions (e.g. by production of *gag–pol* fusions in retroviruses).

The virus classification system known as the Baltimore system (Baltimore 1971) is derived from the obligatory dependence of all viruses on the protein synthesizing machinery of the host cell. Viruses must produce or act as messenger RNA (mRNA) that can be translated by cellular ribosomes. In this classification system the unique relationship of the various forms of the viral genome to mRNA defines virus categories. Class I viruses comprise the double-stranded DNA viruses, class II are the single-stranded DNA viruses, class III are the double-stranded RNA viruses, class IV are the single-stranded positive-sense RNA viruses, and class V are the single-stranded negative-sense RNA viruses. This numbered classification system played a formative role in the development of molecular virology, but is now rarely used. The diverse nature of the viral genome can be rationalized by regarding the genome as an intermediate stage in the cycle of replication of virus nucleic acid that has become sequestered in an extracellular particle. In the Baltimore system a single-stranded RNA molecule is designated as positive sense if it functions as mRNA in protein synthesis, and its complement as the negative-sense strand or anti-message. The retroviruses and some RNA viruses encapsidate the positive-sense RNA strand in the virion, whereas other RNA viruses encapsidate the negative-sense strand or the double-stranded form in the virion. The DNA viruses may be single- or double-stranded, and the positive and negative strands may be encapsidated in separate particles in some of the single-stranded parvoviruses, whereas negative strands are encapsidated exclusively in the recently characterized single-stranded anelloviruses (see

The classification of vertebrate viruses). The only stage in the replication cycle of viral nucleic acids (excluding the replicative intermediates) not represented in known viruses is the RNA:DNA intermediate in the reverse transcription pathway. A small proportion of hepatitis B virus particles, however, do contain DNA/RNA hybrid molecules.

Segmentation of the viral genome

Segmentation of the genome is observed in the arena-, birna-, bunya-, orthomyxo-, and reoviruses. A consequence of segmentation of the genome is the potential for increasing genetic heterogeneity by reassortment of subunits during replication and morphogenesis; the evolution of segmentation in RNA viruses has been equated somewhat fancifully with the evolution of sex, allowing the participation of two, three, or more parents in the production of offspring (Chao 1994). Segmentation and the consequent facility for reassort-

ment may allow the rapid elimination of deleterious mutations and defective genomes. Thus segmentation may be a device evolved to circumvent the assumed limitation on the absolute size of informational RNA molecules imposed by their high mutability. This explanation is difficult to sustain, however, because the total genome sizes of the segmented genome viruses are in the same range as those of nonsegmented genome viruses, and the genome of the largest segmented genome viruses (the 19 kb of the Nairovirus, Crimean–Congo hemorrhagic fever virus) is less than that of the largest nonsegmented genome virus (the 30 kb of murine hepatitis virus, a *Coronavirus*). Segmentation of the genome may more often be a device to facilitate regulation of transcription.

Among mammalian viruses segmentation of the genome is confined to the negative-sense single-stranded RNA viruses and the double-stranded RNA viruses, where the complete complement of genome subunits is contained within a single particle and the infectious unit is a single virion. Segmentation of the genome is common also among the positive-sense single-stranded RNA viruses of plants. These are all multicomponent viruses, however, in which the individual genome subunits are contained in different particles and the infectious unit is a full complement of particles. Genetic reassortment can accompany the maturation of multicomponent viruses and is termed pseudorecombination by plant virologists.

Ambisense encoding of information

Ambisense encoding of genetic information is a phenomenon exhibited by viruses of the family *Arenaviridae*, and by some members of the families *Bunyaviridae* and *Circoviridae*. Ambisense encoding is illustrated diagrammatically in Figure 1. In *Punta Toro virus* (family *Bunyaviridae*, genus *Phlebovirus*) the N polypeptide is encoded in a viral complementary subgenomic RNA corresponding to the 3′ half of the S RNA, whereas the NS protein is encoded in a subgenomic viral sense RNA corresponding to the 5′ half of the genome; thus the S RNA of punta Toro virus is both positive and negative sense. Ambisense encoding of information is common to members of the genus *Phlebovirus*, but is not observed in the other genera of the *Bunyaviridae*. In the family *Arenaviridae* both segments of the bipartite genome exhibit ambisense encoding of information. The large subunit encodes the *L* gene in the 3′ half and the *Z* gene in opposite sense in the 5′ half, and the small subunit encodes the *N* gene in the 3′ half and the *G* gene in opposite sense in the 5′ half. Ambisense encoding may be a device to obtain temporal control of transcription and is not a means of expanding coding capacity.

Reverse transcription, endogenous viruses, and retroid elements

Reverse transcription is not uniquely associated with vertebrate viruses belonging to the families *Retroviridae* and *Hepadnaviridae*. The viruses of plants belonging to the family *Caulimoviridae* also replicate by a reverse transcription route. Comparative analysis of the organization of the RNA associated with vertebrate transposable genetic elements, such as the intracisternal A particles, *VL30* genes and LIMd, and a variety of transposable elements from yeast (Ty), *Drosophila* (copia), *Dictyostelium* (DIRS-1) and maize (B1) revealed structural similarities with the integrated form of the retrovirus genome. Furthermore, the RNA forms of the nucleic acid component of *Drosophila melanogaster copia* transposable element and *Saccharomyces cerevisiae* Ty1 transposable element are present within virus-like particles that have associated reverse transcriptase activity. As a consequence these genetic elements are now ranked as viruses and have been included in the Universal Taxonomy of Viruses as members of a new family – the *Pseudoviridae*

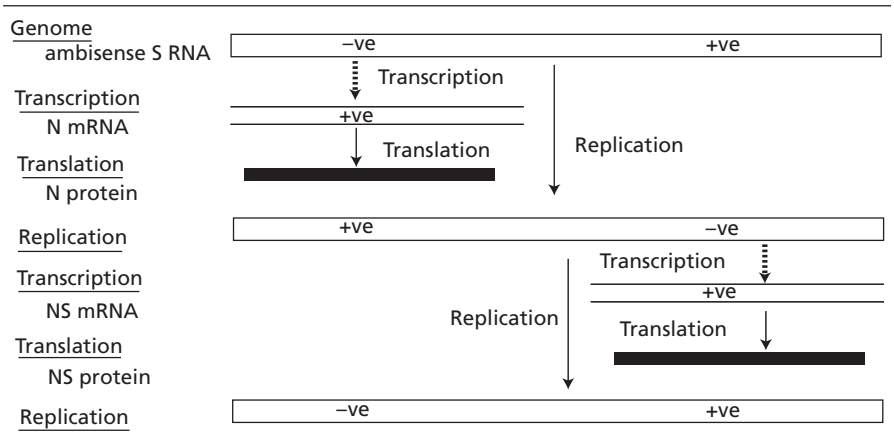

Figure 1 *The ambisense encoding of genetic information in the S RNA of Punta Toro virus,* Phlebovirus *(family* Bunyaviridae*). (After Ihara et al. 1984.)*

(Van Regenmortel et al., 2000; see also The classification of vertebrate viruses).

The common features of the genome maps of these viruses (when linearized in the case of the DNA viruses) are terminal redundancies, which can range from the 17–21 nucleotides of Rous sarcoma virus to the 1123 nucleotides of a human *Spumavirus*, the partial or complete *gag–pol–env* gene order, and the domain structure (protease, reverse transcriptase, integrase) of the polymerase gene. It has been proposed that, during the evolution of these agents, cassettes of genes were added to the basic *gag–pol* core to facilitate adaptation to specific host environments (Hull and Covey 1986). For example, the *env* gene of vertebrate retroviruses is required for protection of the core complex and for cell-to-cell spread, whereas the caulimoviruses have acquired additional genes to facilitate plant-to-plant transmissibility and movement within the plant.

Endogenous retroviruses are defective or nondefective retroviruses transmitted from one generation to the next via the germline, and which probably have evolved in synchrony with their hosts to establish multigenic families. HERVs comprise over 200 distinct groups or subgroups. Although many may have entered the human genome 10–50 million years ago, others appear to have originated from crossinfections at an earlier stage in the evolution of their host. The endogenous feline retrovirus RD114, for example, is thought to have originated as a result of horizontal transfer of an endogenous primate retrovirus, possibly as far back as the Pliocene Age. One view is that HERVs may have played a role in early human evolution by conferring antiviral resistance and altering patterns of gene expression (Sverdlov 2000). Many of the larger mammalian viruses appear to have acquired genes from their host in the course of evolution, but occasionally the reverse can occur. An example is the apparent involvement of a captive retroviral envelope protein, syncytin, in morphogenesis of the human placenta. The syncytin protein is encoded in the *env* gene of a defective endogenous human retrovirus (HERV-W) and its major sites of expression are multinucleate cells in the placenta that originate from fetal trophoblasts. It is presumed that its presence may contribute to normal human placental morphogenesis (Mi et al. 2000).

Infectious nucleic acid

RNA viruses replicate in the cytoplasm, with the exception of the segmented genome orthomyxoviruses and the monopartite negative-sense Bornaviruses (Schneemann et al. 1995), which have nuclear phases. Some others fail to replicate in enucleated cells and are dependent on the presence of a functional nucleus (Pringle 1977). The genome of the positive-sense single-stranded RNA viruses is infectious, because by definition it acts directly on entry as the mRNA for the entire complement of viral proteins, which include the RNA replicase required for replication of the viral genome. The genome of the negative-sense single-stranded RNA viruses, on the other hand, is not infectious because it cannot function as mRNA or be replicated. Mammalian cells do not contain enzymes that can transcribe or replicate RNA templates, and so transcription can be initiated only if the appropriate RNA polymerase is introduced into the cytoplasm of the host cell together with the infecting genome in the form of a nucleocapsid structure.

The DNA of the nuclear DNA viruses is generally infectious, but that of the cytoplasmic poxviruses is not. The poxviruses exhibit the greatest extent of independence of host cell activities of any virus, and the virion contains many enzyme activities, including a viral DNA-dependent RNA polymerase whose presence is essential for infectivity. The discovery of this enzyme by Kates and McAuslan (1967) was crucial to our understanding of the nature of viral genomes and led ultimately to the independent discovery and characterization by Baltimore and Temin and Mitzutani in 1970 of the reverse transcriptase of retroviruses (Baltimore 1971), which is perhaps the greatest single contribution of virology to general biology and which greatly accelerated the exploitation of recombinant DNA technology.

The genomes of retroviruses are also not infectious, probably because preformed virion-associated reverse transcriptase is necessary for initiation of replication. By contrast the proviral DNA form is infectious because it can be transcribed by the host-cell DNA-dependent RNA polymerase to initiate infection. The reverse transcription stage of retrovirus replication takes place in the cytoplasm prior to entry into the nucleus and integration into the host genome.

METHODS OF GENETIC ANALYSIS

Classic genetic analysis of viruses depended on the isolation of spontaneously occurring mutants or the induction of mutations by random mutagenesis followed by nonselective isolation of mutants exhibiting a single conditional lethal phenotype. Further selective screening procedures or systematic characterization of individual mutants were required to identify useful mutations in specific viral genes. Nevertheless, despite the imperfections, many well-defined mutations were identified which played significant roles in the molecular characterization of mammalian viruses, and provisional genetic and physical maps of many viral genomes were obtained by this means (Ramig 1990). The isolation and characterization of revertants is an essential requirement in defining the phenotype of any specific mutant.

Conditional lethal mutants

Conditional lethal phenotypes (temperature sensitivity and host range) have been the favored phenotypes for

the isolation of mutations in essential genes. Other phenotypes, such as plaque morphology, drug resistance, enzyme deficiencies, and spontaneous deletions (sometimes presenting as defective interfering particles), have had application in specific circumstances. The conditional lethal mutants employed in animal virology have been temperature-sensitive mutants, cold-sensitive mutants, or temperature-dependent host range mutants. Host range conditional lethal mutants analogous to the suppressible chain-terminating mutants of bacteriophages (amber or nonsense mutations) have played virtually no role in animal virus genetics, although in principle such mutants allow direct identification of the mutated gene product, because a truncated gene product may be present in the nonpermissive host cell and an intact protein in the permissive cell. Host restriction in animal cells is probably due to the absence of a specific receptor, and permissive mammalian cells naturally able to suppress amber mutations by insertion of an amino acid at an amber stop codon have not been identified. Mammalian cells expressing amber-suppressible tRNAs have been engineered, however, and these have been used successfully to isolate mutations of vesicular stomatitis virus following random mutagenesis (White and McGeoch 1987) and by mutagenesis of poliovirus cDNA in vitro (Sedivy et al. 1987).

Spontaneous mutants and random mutagenesis

Spontaneous mutants occur at low frequency, and a variety of mutagens have been employed to increase the frequency of recovery of mutants. Mutagens that have proved effective with human and animal viruses include base analogues (e.g. 5-fluorouracil and 5-azacytidine for RNA viruses and 5-bromodeoxyuridine for DNA viruses), alkylating agents (e.g. ethylmethane sulfonate, diethyl sulfate), intercalating agents (e.g. proflavine and *N*-nitro-*N*-nitrosoguanidine), deaminating agents (e.g. nitrous acid), hydroxylamine, ultraviolet light irradiation, and miscellaneous agents (e.g. the antiviral agent ribavirin). The base analogues are incorporated into the viral genome and miscoding during replication produces mutations. The other mutagens induce mutations by direct chemical action on the target nucleic acid. The majority of induced mutations seem to be missense mutations whereby substitution of an amino acid modifies the functional activity of a gene product. Frameshift and nonsense mutations of animal viruses are rare. (Practical protocols for random mutagenesis and isolation of mutants are described by Leppard and Pringle (1996).)

Site-specific and directed mutagenesis

These empirical methods described above have been superseded by the adoption of in vitro methods of site-specific mutagenesis. The methodology for constructing such mutants is similar for all DNA and positive-stranded RNA viruses, although there is an operational distinction between viruses whose genome is small enough to be cloned (as a cDNA in the case of RNA viruses) in its entirety (parvoviruses, polyomaviruses, picornaviruses, retroviruses) and those in which mutagenesis is best carried out with a fragment that, after genetic manipulation, is incorporated into a complete genome, generally by recombination in vivo (adenoviruses, herpesviruses, poxviruses).

A prerequisite for directed mutagenesis is a source of molecularly cloned viral nucleic acid. RNA genomes must be first converted to cDNA by reverse transcription and the larger genomes cleaved with an appropriate restriction endonuclease to generate a library of fragments. Once cloned, directed mutagenesis may make use of existing fortuitous restriction sites or employ synthetic oligonucleotides with specific mismatches flanked by regions of complementarity. Then oligonucleotide-directed mutagenesis can be used to obtain point mutations or precisely located deletions. This can be achieved by cloning wildtype genomic DNA into a single-stranded bacteriophage vector (e.g. M13mp19). The single-stranded phage DNA is isolated and annealed to the mutagenizing oligonucleotide that comprises two noncontiguous complementary sequences flanking the region to be looped out to produce the required deletion, or a mismatched base for the production of point mutations. The annealed oligonucleotide acts as a primer for DNA synthesis in vitro and the resulting double-stranded DNA is circularized with DNA ligase. A mutated genome is recovered by repair synthesis on a single-stranded DNA template or, increasingly, by polymerase chain reaction (PCR). (For a generalized protocol for directed mutagenesis, see Leppard and Pringle (1996).)

PCR-based directed mutagenesis has gained the ascendancy in practice because of its greater flexibility. Synthetic primers are designed to locate on opposite strands on either side of the target site. The region targeted for mutagenesis can be further defined by two opposing internal primers, one of which generates the desired mutation while the other eliminates one of two restriction sites flanking the target site. Two-stage amplification yields DNA that can be cleaved at the sites flanking the target site; only mutated DNA should retain the dispensable restriction site (Figure 2). The recovered fragment can then be ligated into an appropriately cleaved plasmid or M13 vector, a process that is facilitated if the restriction sites in the amplified fragment are also unique to the recipient genomic clone. In the case of parvoviruses, polyomaviruses, picornaviruses, and retroviruses, infectious progeny can be generated by direct rescue, i.e. by direct transfection of the reconstructed DNA into susceptible host cells. Transfection of nucleic acid is enhanced variously by

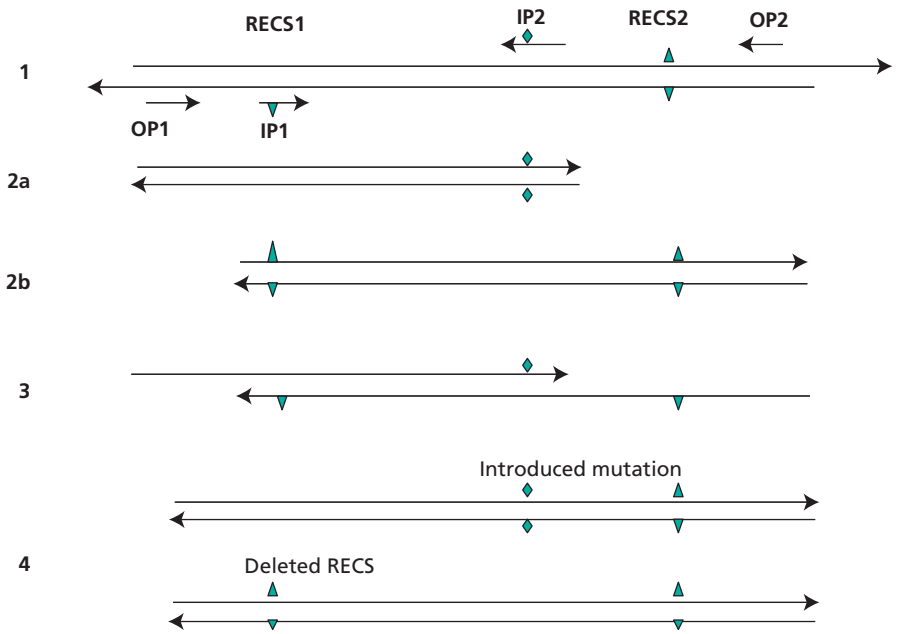

Figure 2 *A generalized two-stage protocol for DNA mutagenesis. OP1, OP2, IP1, and IP2 are oligonucleotide outer (OP) and inner (IP) primers with homology to the target DNA at the positions shown; RECS1 and RECS2 are restriction endonuclease cleavage sites. The inner primer IP2 carries the mutation to be introduced into the target region. All DNA strands are shown with the arrowheads directed towards their 3′ ends. See the text for further explanation. Where only a single mutation is being introduced, a convenient variation of this protocol is to overlap the internal primers, such that each carries the desired mutation (or its homologue). Cleavage of the second-stage PCR product at sites RECS1 and RECS2 will produce a homogeneous mutated DNA fragment.*

calcium phosphate precipitation, lipofection, electroporation etc. Although picornaviruses can be rescued by transfection of cloned DNA, the process is more efficient if RNA transcribed in vitro is transfected by electroporation. For viruses with larger genomes (adeno-, herpes-, and poxviruses), rescue of the mutated fragment into infectious virus is achieved by cotransfection of the mutated sequence and intact viral genomic DNA into permissive cells. Recombination will occur provided the flanking sequences on either side of the mutated site are sufficient to permit homologous recombination. With the intermediate-sized adenoviruses, viral genomic DNA can be inactivated by cleavage with a single-cutting restriction enzyme such that the genome fragments overlap with the mutant-carrying fragment. In this situation infectious virus can be generated only by a process of homologous recombination, and most of the progeny virus will contain the mutation (Figure 3). In the herpesviruses and poxviruses, rescue of directed mutations is mostly confined to genes with phenotypes that are amenable to selection (e.g. enzyme deficiencies, drug resistance, cytopathology) on account of the high background of nonmutated virus in the absence of selection.

Deletion mutants

Operationally, deletion mutants are the simplest to obtain. However, deletion of sequences from a specific protein-coding gene does not always produce a 'null' phenotype. For example, large stretches of the carboxy terminal region of the attachment (G) protein of respiratory syncytial virus can be deleted without affecting the attachment function or the viability of the virus. Similarly, herpesvirus thymidine kinase retains substantial activity despite loss of the first 45 amino acids. Deletion mutant analysis is particularly useful in defining promoter regions. Specific deletions can be engineered by digesting cloned single-stranded DNA from a single-stranded DNA bacteriophage vector with one or two restriction enzymes and recircularizing to generate two circular molecules, the extent and type of deletion obtained depending on the availability of restriction enzyme sites. Sets of deletion mutations can be obtained by restriction enzyme cleavage of a circular DNA molecule followed by progressive extension of a deletion using an exonuclease and recircularization.

Linker scanning mutagenesis

Linker scanning mutagenesis introduces clustered sets of point mutations at desired locations and allows more refined analysis of *cis*-acting control sequences and characterization of protein-binding sites. This procedure allows rapid screening for mutations and their immediate localization as a result of the appearance of a new restriction site (McKnight and Kingsbury 1982). A limitation of deletion mutant analysis is that if the dele-

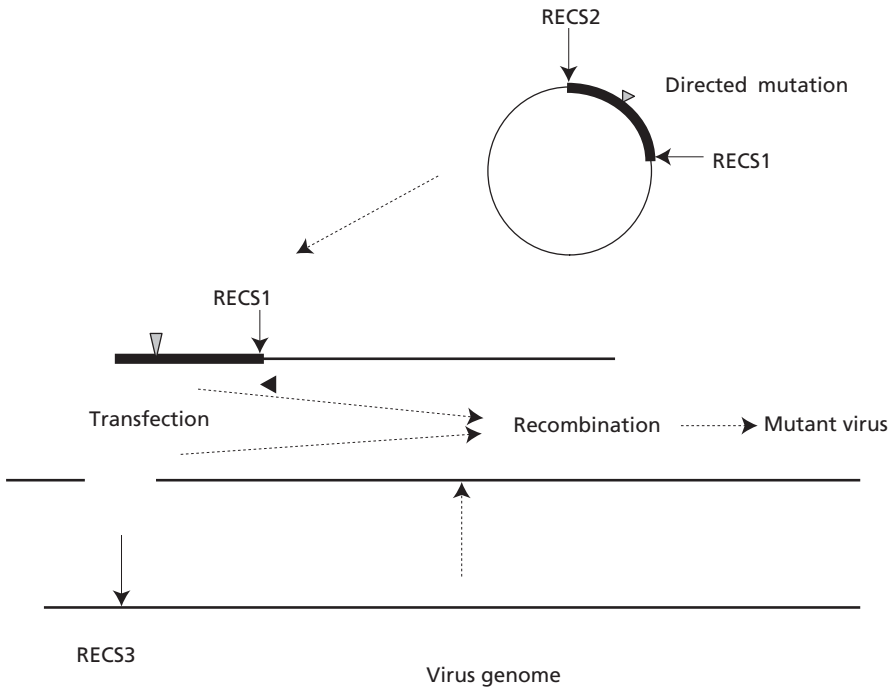

Figure 3 *Rescue of a mutated sequence by recombination. A generalized strategy for introduction of mutations into the terminal region of an adenovirus genome. (Similar strategies can be designed to introduce mutations into other regions of the genome.) The cloned adenovirus terminal genome fragment containing the desired mutation is shown as the thick line. Release of the fragment and cleavage of the target virus genome is achieved by digestion with appropriate restriction endonucleases at sites RECS1 and RESC2, and the products are transfected into appropriate susceptible cells (293 cells in the case of adenovirus). Recombination in vivo results in the generation of infectious virus carrying the desired mutation. (See text for further explanation.)*

tion is large it may cause nonspecific effects, for example steric interactions in proteins, or spacing constraints on promoter function.

Linker insertion mutagenesis

Linker insertion mutagenesis does not involve deletion; a linker is inserted at restriction sites within an open reading frame and many sites can be mutagenized by limiting digestion by a frequent cutting restriction enzyme. A linker of 3 bp (or multiples of 3) will maintain the reading frame beyond the insertion, whereas chain termination can be produced in all three reading frames by insertion of other linkers.

COMPLEMENTATION AND OTHER NONGENETIC INTERACTIONS

Interactions between viruses can be classified broadly as either genetic or nongenetic. Nongenetic interactions include complementation, phenotypic mixing, and interference, and will be considered first.

Complementation

Complementation is the ability of the defective gene product of one virus to be substituted by the normal gene product of another, when both viruses are present in the same host cell. Complementation provides a test for nonidentity, whereby mutants of similar phenotype (e.g. temperature sensitivity) can be assigned to different genes without prior knowledge of the existence or function of those genes. Operationally, complementation is measured in terms of a complementation index (CI). The CI can be used to assess the efficiency of complementation, i.e. in the case of temperature-sensitive mutants, the ratio of yield from a mixed infection (A × B) to the sum of the yields of the single infections (A + B) determined at the restrictive temperature. Progeny virus produced as a consequence of complementation between viruses retains the mutant genotype, because the interaction between viruses occurs at the level of gene products only. Consequently, assay of the progeny from a complementation experiment is carried out at the permissive temperature, and a positive CI indicates nonidentity of function. Complementation is normally intergenic in nature, but in the case of multifunctional gene products (e.g. many viral polymerases) intragenic complementation may be observed.

Complementation analysis has had a prominent role in defining gene function in the papovaviruses, adenoviruses, herpesviruses, poxviruses, retroviruses, alphaviruses, flaviviruses, paramyxoviruses, rhabdoviruses,

arenaviruses, bunyaviruses, orthomyxoviruses, and reoviruses.

Phenotypic mixing and pseudotype formation

Phenotypic mixing is a form of nongenetic interaction between viruses whereby the structural components (capsid or envelope) may be interchanged partially or completely when two different viruses multiply in the same cell. Phenotypic mixing normally occurs between related viruses, but heterologous phenotypic mixing can occur between unrelated viruses. Viruses that are enveloped on exit from the host cell are prone to phenotypic mixing. The mixing of genomes and structural proteins results in the production of progeny virus particles in which the phenotype does not reflect the genotypic properties of the virus. Phenotypic mixing is thus a transient phenomenon.

Pseudotype formation, the complete investment of the core of one virus by the envelope of another, has provided a convenient means of rapid assay of noncytopathic or fastidious viruses. For example, some of the progeny virus released from cells coinfected with the nonfastidious and rapidly cytopathic rhabdoviruses, vesicular stomatitis virus, or Chandipura virus, and a host-restricted and noncytopathic or slowly cytopathic retrovirus will possess the genome of the lytic virus contained within the envelope of the retrovirus. The pseudotype yield, detected as rapidly plaque-forming virus resistant to neutralization by antiserum to the parental lytic rhabdovirus, provides a means of detection and rapid assay of its nonlytic partner. This technique has been used successfully in studies of host range and for detection and assay of HIV-1, HIV-2, HTLV-I, HTLY-II, mouse mammary tumor virus, bovine leukemia virus, and several avian retroviruses.

Many of the oncogenic avian and mammalian retroviruses exist as replication-defective viruses and are dependent on helper leukemia-associated retroviruses. These oncogenic retroviruses often exist as pseudotypes because their envelope glycoproteins are supplied by the helper virus. Other examples of asymmetric complementation or phenotypic mixing are the commensual association of hepatitis D virus and hepatitis B virus and the adenovirus helper dependence of some parvoviruses.

Interference and defective interfering particles

The ubiquity of nongenetic interactions such as complementation and phenotypic mixing is responsible for the prevalence of defective viruses. Defective viruses accumulate in many laboratory-propagated stocks of viruses and are dependent on the presence of their nondefective progenitor for their survival. It is a characteristic of most defective viruses that they specifically interfere with the replication of their helper or closely related viruses. Interference occurs at the level of transcription and replication, and is not interferon-mediated. The mechanism of interference varies between viruses belonging to different families and between different defective viruses of the same virus. For example, the majority of the defective interfering (DI) particles of vesicular stomatitis virus, known as panhandle or hairpin DIs, which contain genomes with complementary 5′ ends and incomplete *L* gene sequences, interfere with the replication of viruses of homologous serotype only, whereas the DI particles that contain internal deletions of the *L* gene interfere with vesicular stomatitis virus of both homologous and heterologous serotypes. In formal terms, a single mutant or nucleotide substitution can constitute a DI genome, and deletion of sequence is not a necessary characteristic. It has been proposed that the generation of DI virus is a natural phenomenon that moderates the course of viral disease and contributes to the self-limiting nature of most viral diseases (Huang and Baltimore 1970). It has been difficult, however, to obtain evidence of the presence of DI virus in natural infections, although in a few instances the administration of DI particles can alter the outcome of an infection. Mice can be protected from an influenza virus-induced immune-mediated pneumonia by the administration of DI particles. However, the DI particles did not reduce the replication of virus in the lung, but seemed to act by preventing the virus-induced T-cell response that is responsible for consolidation (Morgan and Dimmock 1992).

DI particles have been implicated in the initiation, although not necessarily the maintenance, of persistent infection in vivo and in vitro. For example, a DI particle associated with the tsG31 mutant of vesicular stomatitis virus, possessing a 90 percent deletion of the genome, was a good inducer of persistent infection. Indeed, it has been proposed that persistent infection may be an important force in evolution, maintaining genetic variability in those viruses (such as the negative-sense RNA viruses) unable to acquire variation by genetic recombination. The generation of DI virus is a spontaneous mutational event, which in due course forces a mutational response in the parental virus to counteract the DI-mediated interference, and a cyclical phenomenon of alternating generation of new DI and specific DI interference-resistant viruses ensues. Progressive and extensive mutational change over the whole genome was observed to accompany the propagation of the normally lytic vesicular stomatitis virus as a persistent nonlytic infection in cultured cells, whereas by contrast the virus is genetically stable during cycles of lytic infection. The extensive mutation of the measles virus genome observed in the defective viruses recovered from the brain of patients with subacute sclerosing panence-

phalitis (SSPE) may be an indication that this phenomenon plays a role in human disease processes.

GENETIC INTERACTIONS

Genetic interactions include recombination, subunit reassortment, and multiplicity reactivation. Their characterization provides information about the evolutionary potential of viruses as well as means of their experimental manipulation.

Recombination in DNA viruses and positive-sense RNA viruses

Recombination occurs as a consequence of the physical interaction of viral genomes in the infected cell. It is a phenomenon common to all DNA-containing viruses, both DNA-containing and RNA-containing retroviruses, and most positive-strand RNA viruses. Recombination between DNA genomes is probably a conventional intramolecular mechanism involving a breakage and reformation of covalent bonds, whereas recombination between RNA genomes is a process mediated by a template switching ('copy-choice') mechanism during minus-strand synthesis. The probability of occurrence of a recombinational event between two genes is proportional to the physical distance separating them on the genome, and genetic maps can be constructed on the basis of recombination frequencies. Temperature-sensitive (ts) mutants have formed the framework for most genetic maps. The recombination frequency (RF) between any pair of temperature-sensitive mutants, A and B, is measured as the frequency (percentage) of wildtype virus generated in multiple infections, such that the RF between any two temperature-sensitive mutants, A and B, is measured as a frequency (percentage), such that $RF = 2 \times 100 \times \text{yield } (A + B)^{RT} - (\text{yield } A^{RT} + \text{yield } B^{RT})/\text{yield } (A + B)^{PT}$, where RT is the restrictive temperature and PT the permissive temperature. The single and mixed infections are carried out at the permissive temperature and yields assayed at the temperatures indicated by the superscript. The factor 2 is included because only the wildtype recombinant is measured by this assay, and it is assumed that the reciprocal recombinant (the double ts mutant) occurs with equal frequency. Using a quantitative PCR assay, Jarvis and Kirkegaard (1992) confirmed that frequencies of the reciprocal recombinants in poliovirus recombination are equivalent, but only when the parental input multiplicities are identical. Linear genetic maps of several DNA viruses (adeno-, herpes-, pox-, and picornaviruses) have been constructed on the basis of two factor crosses to establish relative proximity and three factor crosses to confirm orientation (for a detailed account, see Ramig 1990).

Mutants classified in the same complementation group cluster in the map, and the greatest distance separating mutants in the cluster defines the minimum size of the gene. In the adenoviruses and herpesviruses intertypic crosses, in which the parental ts mutants are derived from viruses of different serotype, have been employed to confirm the linear order of the genetic map and to show that the genetic and physical maps of the genome, constructed on the basis of restriction endonuclease fragment analysis or direct sequencing, are colinear. Recombinants between herpesvirus types 1 and 2 have been isolated from cultured cells, but natural recombinants have not been recovered from patients, suggesting that there are selective constraints preventing such interactions. Paradoxically, although the frequency of recombination is generally lower, natural recombinants occur more frequently in RNA viruses. For example, intertypic recombinants are prominent in the virus recovered from children after vaccination with the trivalent Sabin vaccine, although none of these recombinants has as yet escaped the immune response of the host to become established in nature. Rare heterologous recombinants also occur: for example, the *Alphavirus* known as Western equine encephalitis virus seems to be a recombinant of another *Alphavirus*, Eastern equine encephalitis virus, and a New World relative of Sindbis virus (Hahn and Lustig 1988).

Recombination in RNA viruses is not universal (reviewed by Lai 1992; Wimmer et al. 1993). Low-frequency genetic recombination (up to 0.9 percent) occurs in viruses with positive-strand genomes, and linear genetic maps were derived for both poliovirus and foot-and-mouth disease virus, which were subsequently found to be colinear with physical maps. Homologous recombination does not seem to be site specific, although intertypic recombination in poliovirus and foot-and-mouth disease virus may be influenced by local structural features. The three poliovirus types differ by about 15 percent in their nucleotide sequences, and the frequency of recombination observed between viruses of different subtypes, as expected by a template switching (copy-choice) mode of recombination, is about 100 times less than between viruses belonging to the same serotype.

Large genome sections can be transposed as a result of natural recombination in vivo, and the characterization of the phenotypic properties of recombinants has played a prominent role in the mapping of attenuating mutations in the Sabin poliovirus vaccine strains. Transposition of segments of any size can now be achieved in a more controlled manner by exchange of segments between existing or engineered restriction sites in infectious cDNA clones. This approach also provides a means of direct verification of the association of particular mutations with a specific phenotype. For example, a poliovirus mutant carrying a four-base insertion at position 70 within the 5′ untranslated leader region has a small plaque ts phenotype and is deficient in RNA synthesis. Revertants of this mutant retained the four-

base insert, and mix-and-match experiments with cDNA located these second site suppressor mutations to a site within the 3C protease gene (Andino et al. 1990). The isolation and characterization of revertants is an essential feature of the characterization of any mutant. The same approach can be used to produce chimeric viruses in order to study the homology and functional compatibility of genetic elements. For example, it has been shown that the 5′ untranslated leader regions of poliovirus and a coxsackie B virus can be interchanged.

The 5′ untranslated region of the genome of picornaviruses contains an internal ribosomal entry site (IRES), and poliovirus can be transformed into a vector by insertion of a foreign gene between tandemly arranged IRES sequences, in which one is derived from a nonhomologous IRES (e.g. from encephalomyocarditis virus (EMCV)) to prevent loss by homologous recombination. A dicistronic virus mimicking the genetic organization of the plant picornavirus cowpea mosaic virus (CPMV) can be created by insertion of the IRES from EMCV between the capsid precursor coding region and the nonstructural protein coding region of the poliovirus genome. Unlike CPMV, however, the two transcriptional units are linked and contained within the same particle.

Exceptionally, high-frequency genetic recombination is observed in mixed infections of coronaviruses, but a linear map of the coronavirus genome has not been produced. This may be a consequence of the complexity of the organization of the *Coronavirus* genome, with its unique 'nested set' configuration of genetic information, whereby subgenomic RNAs with a common 3′ terminus and differential extensions in a 5′ direction are intermediates in mRNA transcription. In addition, the polymerase protein of coronaviruses is encoded in two large open reading frames, from which the gene product is derived by translational frameshifting (ribosomal slippage). The largest *Coronavirus* genome (approximately 31 kb) is much larger than the picornavirus genome (approximately 7.5 kb), but the rate of recombination per nucleotide is similar at approximately 0.1 percent per 100 nucleotides (Lai 1992).

Reverse transcription and recombination

The retrovirus genome is present in the virion in a pseudodiploid form. Two copies of the viral genome are associated head-to-head by hydrogen bonding between short repeats at their 5′ ends. Despite the fact that two genomes are encapsidated in a single virion, only a single provirus is generated under conditions of infection of cells by single virions. The reason for the unique pseudodiploid form of the genome is unknown, except that it does allow for damage repair by recombination during the reverse transcription process. In other viruses replication is generally accompanied by amplification of the genome, whereas in the replication of retroviruses there is no net gain; the process of reverse transcription results in the conversion of a one pair of single-stranded RNA genomes into one double-stranded DNA provirus (the process has been described as destructive replication). Reverse transcription not only generates a linear DNA copy of the retroviral genome but also produces the long terminal repeats (LTR), which contain the signals necessary for transcription of the integrated DNA, and which together are designated the provirus. At the cell–virus DNA junction there is a 5-bp direct repeat of cellular DNA next to a 3-bp inverted repeat of viral DNA, a structure similar to that present at the termini of several bacterial transposons. A major distinction between the retroviruses and other nuclear DNA viruses is that the former maintain productive infections and do not usually kill the host cell, whereas the latter invariably destroy their host cell and can only become stably integrated in a nonproductive form. (The phenomenon of latency in herpesviruses, however, to some extent blurs this distinction.)

High-frequency recombination is an inherent consequence of retrovirus replication. In crosses of exogenous retroviruses, recombination has been detected both between and within genes and between exogenous and endogenous viruses. The pseudodiploid nature of the genome means that heterozygous genomes can exist and may be intermediates in the generation of stable recombinants. In the replication of retroviruses, the location of the tRNA primer for DNA synthesis near the 5′ ends of the tandemly associated monomers means that the reverse transcriptase must transfer from the 5′ end of one monomer to the 3′ end of the same or the other monomer soon after the initiation of synthesis. Thus every round of synthesis is effectively a recombinational event. Furthermore, the process of reverse transcription itself involves synthesis of negative-strand DNA on the genomic positive-strand RNA template, and simultaneous degradation of the RNA template by the ribonuclease H activity of the enzyme complex, followed by synthesis of a positive DNA strand with internal discontinuities on the negative-strand template. There are abundant opportunities for recombination, either during negative-strand synthesis by a copy choice mechanism, or during positive-strand synthesis by strand displacement and assimilation on to replicating DNA from another genome. Comparison of the inferred amino acid sequences of retroviral proteins suggests that recombination has played an important role in the diversification of the envelope proteins of retroviruses, whereas the polymerase gene seems to have been protected from functionally disruptive recombinational events (McClure et al. 1988).

The extreme variability of the surface proteins of HIV-1 is not mediated by recombination alone. Progressive mutational change plays a role in addition to recombinational events, as does the phenomenon of biased

hypermutation (Martinez et al. 1994), see later under Biased hypermutation.

Multiplicity reactivation, marker rescue and cross-reactivation

Multiplicity reactivation occurs when cells are infected with parental viruses which themselves are noninfectious (usually as a result of UV irradiation). At higher multiplicities of infection progeny virus may be released from susceptible cells that contain markers contributed by both parents. Infectivity has been restored by replacement of defective genes by recombination (or reassortment). Multiplicity reactivation is observed only if the inactivating lesions in the two parental viruses are located in different genes. Multiplicity reactivation has been observed between strains of the same virus, and also between viruses of different serotypes. Reactivation between an inactivated parent and an infectious parent is termed crossreactivation, or marker rescue, and is likewise mediated by recombination (or reassortment). Cross-reactivation can be exploited to increase the yield of recombinants (or reassortants) by infecting susceptible cells with a nonplaque-forming virus and a UV-inactivated plaque-forming virus.

Reverse genetics of double-stranded and negative-sense single-stranded RNA viruses

Intermolecular recombination has not been demonstrated unequivocally for any RNA virus with a negative-strand or double-stranded genome, with the exception of the tripartite genome double-stranded RNA phage ϕ6 (Mindich 1995). It is likely that recombination can occur as a rare event; otherwise it is difficult to account for the origin of some of the DI viruses of vesicular stomatitis virus, influenza A virus, and rotavirus which have truncated and juxtaposed genes, or rare phenomena such as the inversion of genes in the mammalian pneumoviruses, which departs from the otherwise invariant gene order found in other paramyxoviruses.

The double-stranded RNA viruses can exchange genes by reassortment of genome subunits. However, the development of a reverse genetics system to allow controlled mutagenesis of individual genome subunits has proved unexpectedly difficult to achieve. Roner and Joklik (2001) have recently described a reverse genetic system for reovirus type 3, which may be generally applicable to other members of the family *Reoviridae*.

The single-stranded negative-sense RNA viruses as a group do not exhibit genetic recombination, apart from the phenomenon of subunit reassortment in those viruses that have segmented genomes. For long this prevented the application of molecular genetic analysis to the negative-sense RNA viruses, which include many important animal and human pathogens. However, reverse genetic systems are now available for many members of the nonsegmented genome families *Filoviridae*, *Paramyxoviridae*, and *Rhabdoviridae*, and the segmented genome families *Bunyaviridae* and *Orthomyxoviridae* (reviewed by Neumann et al. 2002). The genomic RNA of negative-strand RNA viruses is not infectious because the negative strand is not translated. However, Luytjes et al. (1989) achieved amplification, transcription, and rescue of synthetic RNA molecules by reconstitution of a biologically active nucleoprotein complex using synthetic RNA and purified core proteins in the presence of helper influenza virus. The packaging of the larger genomic RNAs of the nonsegmented genome viruses (the order *Mononegavirales*) also presented difficulties. The breakthrough came with the construction of a complete infectious cDNA copy of the genome of rabies virus by Schnell et al. (1994), and infectious cDNA clones for many viruses are now available.

Strategies for rescuing negative-sense RNA virus genomes rely on transfection of the cloned copy of the viral genome (usually as the anti-genome) into susceptible host cells, together with a source of T7 RNA polymerase, usually provided by a vaccinia virus recombinant vector, to direct the synthesis from bacteriophage T7 transcription plasmids of RNAs encoding the components of the viral nucleocapsid complex (Figure 4). The cloned anti-genomic strand is terminated with a ribozyme sequence. Self-cleavage of the primary transcript then removes the ribozyme sequences, leaving a precise 3′ terminus. The newly transcribed nucleocapsid components first replicate the anti-genomic RNA and then transcribe the newly synthesized negative strand. This results in production of the remaining structural proteins, further replication, and packaging as in a normal infection. Initially it was presumed that expression from an anti-genomic template, rather than genomic RNA, was obligatory to avoid sequestration and functional loss of the L, M, and P mRNAs of rabies virus by annealing to genomic-sense RNA. However, this is not an absolute requirement, and Sendai virus has been rescued from genomic DNA, albeit with reduced efficiency.

Reverse genetic systems for segmented genome viruses were more difficult to exploit because of the difficulty of delivering multiple genomic RNAs. The first successful reverse genetic system was achieved with the tripartite Bunyamwera virus, adapting the methodology developed for nonsegmented genome viruses. Later modified procedures were developed for the reverse genetics of the eight-segmented influenza A virus and influenza B virus, which take account of the nuclear phase in the replication cycle of these viruses. Figure 5 illustrates the methodology for the genetic manipulation

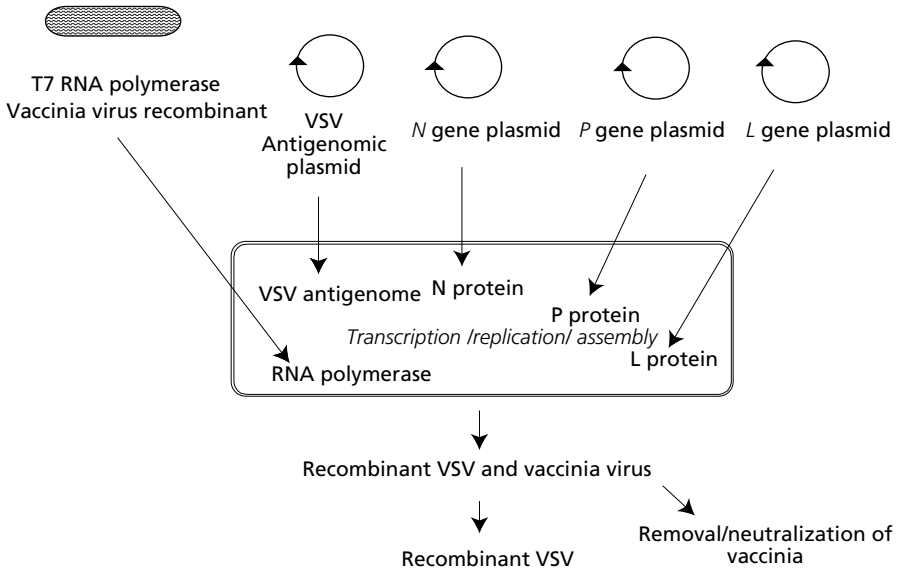

Figure 4 *Reverse genetics of nonsegmented negative-sense RNA viruses. The diagram depicts the strategy used to rescue infectious virus from the cDNA clone of a negative-sense RNA virus with a nonsegmented genome: vesicular stomatitis virus (VSV) is used as the example. Plasmids expressing the N, P, and L constituent proteins of transcribing nucleocapsids, and a plasmid containing a full-length cDNA replica of the viral antigenome, all under the control of the T7 RNA polymerase promoter (→), are transfected into susceptible cells. The T7 RNA polymerase is provided by coinfection of the cell substrate with a recombinant vaccinia virus expressing the T7 RNA polymerase. This is sufficient to initiate synthesis of functional nucleocapsids, followed by transcription, replication, assembly, and release of infectious virus.*

and recovery of negative-sense RNA viruses from cDNA clones of segmented genome viruses.

Recombination with host transcripts

Functions essential to replication and maturation can be attributed to no more than half the genes of the herpes simplex virus genome. It is likely that some of the excess coding capacity of the large DNA viruses represents accretion and modification of host genetic material by recombination. It is clear also that the oncogenic retroviruses have acquired their oncogenic potential by incorporation of cellular oncogenes by a recombinational mechanism. It is perhaps surprising, in view of the obligatory proviral phase in the multiplication cycle of these viruses, that these events have been so rare and restricted to experimental propagation of viruses in an inappropriate host.

Although conventional RNA viruses might not be expected to interact with the host-cell genome, there are isolated instances of such interactions for several positive-sense RNA viruses (poliovirus, Sindbis virus, and bovine viral diarrhea virus) and the negative-sense influenza A virus. The latter is the most exceptional because negative-sense RNA viruses do not exhibit intermolecular recombination. None the less, a variant of influenza A virus exists whose *N* gene subunit has an additional sequence exhibiting homology with host ribosomal RNA sequences. Best documented are the several independently derived isolates of the *Pestivirus*, bovine viral diarrhea virus (BVDV), which have acquired simultaneously a cytopathic (cp) and a virulent phenotype. Molecular analysis of these events suggested that each cp virus evolved from the pre-existing noncytopathic (noncp) virus by a process of RNA recombination. A mechanism based on template switching of the viral polymerase during negative strand synthesis has been proposed to explain this phenomenon. Nonstructural protein NS3 is found exclusively after infection with cp BVDV, whereas uncleaved NS2-3 is characteristic of persistent noncp virus. The mutations that lead to the generation of NS3 from the polyprotein precursor include the precise insertion of cellular sequences, frequently together with large duplications and other genomic rearrangements. Two different kinds of cellular insertion have been identified, either (poly)ubiquitin or part of a cellular polypeptide of unknown function. Cleavage of the polyprotein at the N terminus of NS3 can be mediated by any of the several proteases that cleave ubiquitin in uninfected cells (Meyers and Thiel 1996). The expression of NS3 protein was considered to be strictly correlated with the cp phenotype, but later Qu et al. (2001) isolated a series of non-cp mutants from cp virus that still expressed NS3 protein. Sequence analyses of these noncp revertants uncovered no change in NS3, but all exhibited a single substitution in the NS4B region. Although the mechanism remains to be elucidated, these results illustrate that mutations in NS4B can attenuate BVDV cytopathogenicity despite NS3 production.

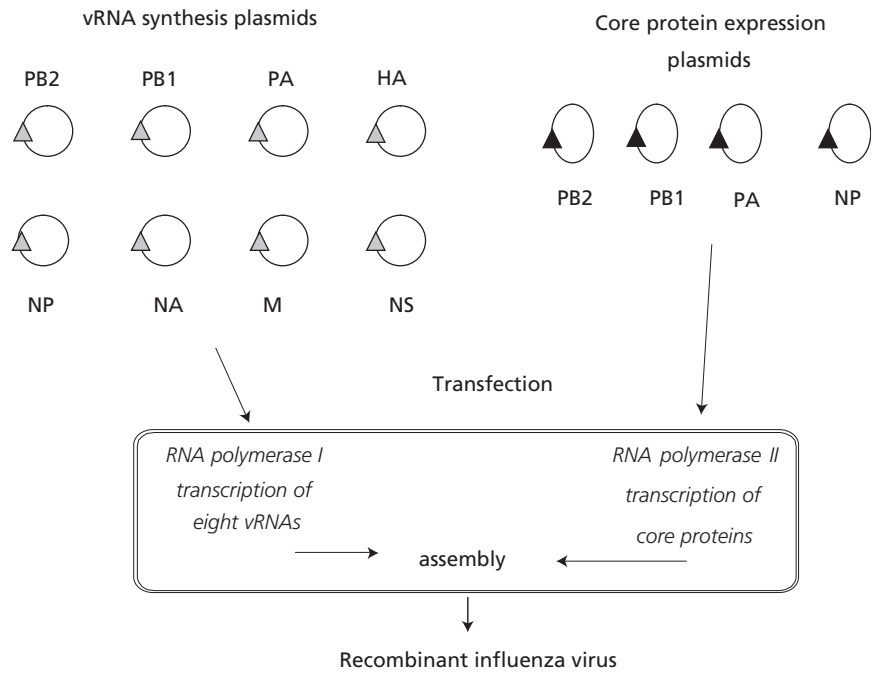

Figure 5 *Reverse genetics of segmented genome negative-sense RNA viruses. The diagram depicts the strategy used to rescue infectious virus from cDNA clones of the genome segments of a negative-sense RNA virus; influenza A virus is used as the example. Susceptible cells are transfected with plasmids encoding all eight components of the negative-sense genome under the control of the RNA polymerase I promoter (gray arrow-heads), together with four plasmids expressing the nucleocapsid components (PB1, PB2, PA, and NP) of influenza virus under the control of the RNA polymerase II promoter (black arrow-heads). The viral genomic RNAs are synthesized by cellular RNA polymerase I, and replication and transcription are initiated by synthesis of the viral polymerase (PB1, PB2, and PA) and the nucleoprotein (NP), followed by assembly and release of infectious virus.*

Interactions between cellular RNAs and replicating viral RNA have also been demonstrated in plant viruses, where a replication-competent deletion mutant of CPMV was rescued by recombination in transgenic plants expressing the deleted sequences (Greene and Allison 1994).

Subunit reassortment

All the segmented genome RNA viruses of animals are able to exchange genetic information by a process of subunit reassortment. Reassortment occurs at high frequency between related viruses; for example, all influenza A viruses are able to exchange genome subunits, but influenza A, B, and C viruses do not interact. In the bunyaviruses and the reoviruses restriction on reassortment of genome subunits closely parallels the serological and sequence relationships of the viruses, and does not correlate with the geographic origin of the isolates. In the orthomyxoviruses it is probable that there is random (i.e. unlinked) association of genome subunits and that the low electron microscope particle/plaque-forming unit ratio is a reflection of the imprecision of the maturation process, whereby only some particles receive the essential complement of eight unique subunits.

In the bunyaviruses, with their tripartite genomes, it is possible to undertake complete progeny analysis, because there are only six (2^3–2) nonparental reassortant genotypes, in contrast to the 254 (2^8–2) of influenza A virus, to be assayed. Reassortment appears not to be random and there are preferred associations of subunits even in the case of closely related viruses. The mechanism of restriction appears to operate at the level of gene products, as the terminal sequences of the subunits are identical and do not exhibit the specificity required for nonrandom reassortment. However, in crosses of Bunyamwera virus and Maguari virus, which belong to the Bunyamwera serogroup, once a parental subunit configuration had been broken by reassortment, the restriction on reassortment among progeny virus genomes was relaxed (Pringle 1996).

In the reoviruses, where maturation is efficient and precise, and particle/infectivity ratios are close to unity, reassortment appears to be random. In sharp contrast, if cells were infected (by lipofection) with reovirus infectious cores rather than virions, the progeny was almost exclusively monoreassortant virus (i.e. virus with nine subunits from one parent and one from the other). Lipofection of cells with naked RNA permitted only assortment (i.e. recovery of parental virus), not reassortment (Joklik and Roner 1995). These observations emphasize the complexity of the reassortment process

and suggest again that protein–protein interactions, rather than RNA-sequence recognition, determine the specificity of reassortment. A complicating factor in the analysis of reassortment, described in rotavirus progeny analysis but probably true for all segmented genome viruses, is that the phenotype of the reassortants recovered may be modified by the genetic background of the recipient (Chen et al. 1989).

In general, reassortment is restricted to taxonomically related viruses: in the family *Orthomyxoviridae* the boundaries are defined by species, and by serogroups within species in other virus families. Conversely, genetic compatibility, as measured by the ability to reassort genome subunits, may be a useful approach to equating taxons in different virus families. All segmented genome viruses have the potential for rapid adaptation to new hosts, for abrupt generation of viruses with new antigenic characteristics, and for sudden extensions of host range and virulence. Transmission by vectors and multiplication in alternate hosts are also common features of these viruses.

Genetic reassortment plays a major role in the epidemiology of human influenza. Mutation accounts for the progressive genetic and antigenic variation (antigenic drift) of influenza A virus during interpandemic periods, but the appearance of new pandemic strains usually requires the introduction of new genes by reassortment (antigenic shift). Avian viruses seem to provide the reservoir of antigenic variation from which new pandemic strains can be generated. Much evidence suggests that the pig provides the 'mixing vessel' in which avian and human viruses can interact, generating progeny with new antigenic properties and the constellations of genes required to allow transmission to and spread within human hosts. In South China the domestic duck may be the intermediate host carrying viruses from feral ducks to the pig, whereas in North America domesticated turkeys may be a more important intermediate host. Reassortment of influenza A virus seems to have been responsible for the major pandemics afflicting the human population since the beginning of the twentieth century. However, a recent outbreak of a lethal antigenically novel avian-like virus in horses in the Far East, and since 2003 the appearance of various avian influenza A viruses in humans (H5N1 in East Asia, H7N7 in the Netherlands, H7N3 in Canada, and H7N2 in the USA), indicate that avian viruses can spread directly to mammalian species without the need for reassortment or passage through an intermediate host.

Superinfection exclusion and gene capture

The three serotypes of reoviruses exchange genome segments freely during mixed infection both in vitro and in vivo, but little is known about the role of reassortment in the biology of these viruses. In some segmented genome viruses (e.g. some bunyaviruses and orbiviruses), but not in others (e.g. rotaviruses), a phenomenon of superinfection exclusion is observed whereby a superinfecting virus is able to participate in subunit reassortment for only a limited period after primary infection. Superinfection exclusion is also host-dependent. For example, reassortment of the genome subunits of the *Orbivirus*, bluetongue virus, is inhibited if the introduction of the superinfecting virus is delayed by more than 4 h, whereas there is no interference for a period of at least 5 days in asynchronously infected midges.

Natural reassortants of rotaviruses are probably frequent in occurrence, and there is ample evidence for gene capture by the interaction of segmented genome viruses present in alternate hosts. For example, the Au-1 strain of human *Rotavirus* has a VP-4-coding subunit encoding a feline *Rotavirus*-like VP-4, suggesting that genetic interaction between feline and human rotaviruses is not infrequent. Other rotaviruses recovered from humans seem to be reassortants of human, bovine, and a third unidentified parental rotavirus. Likewise, it has been implied that the five serotypes of bluetongue virus present in North America are derived from three distinct gene pools, and that serotype 17 has evolved by a combination of reassortment and genetic drift.

VIRUS VARIABILITY

Like all biological entities that posses the ability to replicate and reproduce themselves, viruses are endowed with an intrinsic variability derived from the error-prone process of nucleic acid replication. This inbuilt variability enables viruses to respond to selective forces and ultimately guarantees their survival.

The quasi-species concept

It is generally accepted that mutation frequencies in most RNA viruses are very high, ranging from 10^{-3} to 10^{-6}, and usually in the range 10^{-4} to 10^{-5}. Consequently, a 10-kb RNA genome will on average carry one or more mutations, and any population of RNA viruses will comprise a heterogeneous swarm of diverse mutants. The term quasi-species was introduced to take account of this phenomenon and the consequent difficulty of defining a viral species (Eigen and Biebricher 1988). A single 'master' sequence may predominate at any one time during replication in a defined environment, but its existence will be transient and dependent on the maintenance of strong external selective forces. The high mutation frequencies of RNA viruses are attributed to the inherent error-proneness of RNA-dependent RNA polymerase and reverse transcriptase, and to the lack of a proofreading function.

Paradoxically, some RNA viruses exhibit great sequence stability during replication in vivo or during

propagation in cultured cells. Even the highly variable HIV-1 is more stable during replication in cell culture than the error-proneness of the purified polymerase would predict, indicating the existence of cellular stabilizing factors (Mansky and Temin 1995).

Although the high mutation rates of RNA viruses provide them with great adaptability and may explain why in recent times they have been causes of emerging diseases (e.g. hepatitis C virus, Nipah virus, Hendra virus, severe acute respiratory syndrome (SARS) *Coronavirus*, enterovirus 71, and others) their limited genome size means that they are also subject to major evolutionary constraints. Also gene duplication and lateral gene transfer from their host or other viruses are inherently less likely (Holmes and Rambaut 2004).

Hypermutation

Enhanced frequency mutation mediated by an error-prone polymerase has been described for vesicular stomatitis virus (Pringle 1987). Also, hypermutable sites occur in genomes, such as those generating frameshift and other mutations in the attachment (G) protein gene of human respiratory syncytial virus (Cane et al. 1993). Likewise, in DNA viruses mutations in accessory DNA replicating functions have been shown to be responsible for effects on the mutation frequency of herpes simplex virus type 1 (HSV-1) in cultured cells. Mutational loss of HSV-1-encoded dUTPase activity resulted in a fivefold increase in the relative mutant frequency, whereas thymidine kinase-negative mutants reduced the relative mutation rate up to 40-fold (Pyle and Thompson 1994).

Biased hypermutation

Several instances of biased hypermutation have been described. A phenomenon of G→A hypermutation has been observed in retroviruses and hepadnaviruses. Among negative-sense single-stranded RNA viruses, biased A→I hypermutation has been observed to affect mainly the matrix protein gene of measles virus, possibly as a consequence of posttranscriptional enzymatic misreading of A residues (Billeter and Cattaneo 1991); and multiple A→G transitions occur in the attachment protein gene of human respiratory syncytial virus. The latter are characteristic of neutralization escape mutants selected with monoclonal antibodies against the conserved central region of the G protein (Martinez and Melero 2002). A high frequency of frameshift mutations was observed also in the same gene, mediated by the addition or deletion of adenosine residues in some, but not all, runs of such residues. The fidelity of the viral polymerase appeared to be dependent on the template sequence (Cane et al. 1993).

The biased hypermutatiion in which many U residues were substituted by C residues, predominantly in the *M* (matrix) protein gene of measles virus, was characteristic of isolates of measles virus associated with neurologic conditions such as subacute sclerosing panencephalitis and measles inclusion body encephalitis (MIBE). In the extreme case, 54 percent of U residues were changed to C residues. The phenomenon may be mediated by the presence in the cytoplasm of neural cells of a double-stranded RNA unwindase, an enzyme normally abundant in nuclei. This enzyme (duplex RNA-dependent adenosine deaminase) converts adenosine to inosine ribonucleotide. It is hypothesized that the predominance of U→C misincorporations over A (to I)→G mutations is a consequence of the formation of double-stranded RNA molecules by localized collapse of transcribed mRNA on to the genomic- (negative-) strand template, whereas the collapse of replicating negative-sense RNA on to the positive-sense anti-genome would be less frequent because of the encapsidation of replicating molecules, which is a feature of the synthesis of negative-strand RNA viruses. The phenomenon seems to have clinical significance in that clonal expansion of hypermutated measles viruses was demonstrated throughout the brain of an SSPE patient (Baczko et al. 1993).

Retroviral G→A hypermutation takes place during reverse transcription when the intracellular dTTP concentration greatly exceeds that of dCTP (Vartanian et al. 1997), This results in extensive incorporation of dT opposite rG, leading to G→A substitutions. In vitro the extent of G→A hypermutation can be influenced by manipulation of the dTTP/dCTP ratio. The extreme of such biased hypermutation is observed in the lentiviruses, where misincorporation may reach 60 percent in short stretches. It occurs predominantly during negative-sense DNA strand synthesis, and it has been established that G→A hypermutation can be sustained throughout synthesis of the entire 10-kb negative-sense DNA strand of HIV type 1, resulting in substitution of approximately 31 percent of the G residues (Vartanian et al. 2002).

Gunther et al. (1997) have described two naturally occurring hepatitis B virus genomes from a chronic carrier which exhibited G→A mutations distributed across the whole genome, with a strong dinucleotide preference in the order GpA > GpG > GpC/GpT. The frequency of replacement of guanosine residues by adenosine was 12 and 26 percent. The detection of hypermutation in natural isolates of hepatitis B virus suggested that a minority of hepatocytes might have distorted dNTP pool which, as well as generating hypermutation might be reflected in the fidelity of hepatocyte DNA synthesis and repair.

APPLICATIONS OF GENETIC ANALYSIS IN VIROLOGY

A genetic approach has many actual and potential applications in virology: for example, considered here are the

analysis of antigenic properties (epitope mapping), identification of determinants of virulence and drug resistance, interpretation of molecular epidemiology, and the engineering of live virus vaccines.

Epitope analysis

Neutralization escape mutants can be isolated following exposure to, or growth in the presence of, a specific antiserum or an appropriate monoclonal antibody. Specific epitopes can be identified by analysis of the reactivity of neutralization escape mutants with panels of monoclonal antibodies. These epitopes can then be located by nucleotide sequencing of the escape mutants and physical mapping of the mutational changes. Optimally, these changes can then be located on the three-dimensional structure of viral attachment proteins (e.g. the HA protein of influenza A virus; see Orthomyxoviruses: influenza) or the whole virion (e.g. poliovirus; see Picornaviruses).

Nonneutralizing monoclonal antibody escape mutants can be obtained by a modification of the selection technique. Infected cell monolayers are reacted with an appropriate murine monoclonal antibody and then treated with an enzyme-linked second antibody (e.g. a horseradish peroxidase rabbit anti-mouse polyclonal serum). Plaques that are unstained represent monoclonal antibody-resistant (MAR) mutants, which can be employed in analysing the antigenic properties of nonstructural and internal components of viruses.

Drug resistance

The isolation of drug resistance mutants can identify the site of action of an antiviral agent and assist in analyzing both the mechanism of action of the drug and the function of the target protein. For example, identification of the function of the M2 protein of influenza virus and confirmation of its presence in the virion were direct results of the isolation of amantidine-resistant mutants of influenza A virus (Hayden and Hay 1992).

The isolation of drug resistance mutants can also provide information of relevance in the treatment of viral disease. For example, molecular analysis of mutants of HIV-1 virus resistant to 3′-azido-3′-deoxythymidine (AZT), nucleoside analogues, and other nonnucleoside reverse transcriptase (RT) inhibitors revealed unpredicted interaction between drugs in patients. In particular, suppression of phenotypic AZT resistance was observed in some viruses with mutations in the RT gene, which conferred resistance to other anti-retroviral drugs. Other combinations of mutations conferred co-resistance. A conclusion from such analyses is that certain combinations of antivirals are more likely than others to induce multidrug resistance in the patient, and that it may be possible to design treatment schedules to reduce this possibility, and even perhaps to reverse the loss of efficacy of AZT (Larder 1994).

Identification of virulence determinants

Analysis of the determinants of the virulence of the three Sabin poliovirus vaccine strains, which were produced by a process of adaptation to growth in nonneural tissue in vitro, provides one of the best examples of the potential of genetic analysis.

Determination of the complete sequence of the type 1 Sabin vaccine strain and its Mahoney virulent progenitor revealed that 56 single-site mutations, resulting in 21 amino acid substitutions, differentiated the two strains. The production of intratypic and intertypic recombinants generated by recombination experiments, the construction of in vitro clones from cDNA, and site-directed mutagenesis led to the conclusion that several mutations, mapped to VP1, VP3 , VP4, $3D^{pol}$, and the 3′ noncoding region, contributed to the attenuation and temperature-sensitive phenotypes. Although there was a strong correlation between the rct (temperature sensitivity) phenotype and loss of neurovirulence, assay of these recombinants and mutants in transgenic mice expressing the human poliovirus receptor revealed that the determinants of temperature sensitivity and attenuation were separable genetically (Bouchard et al. 1995).

A similar analysis was not possible with the poliovirus type 2, because the progenitor was already avirulent in monkeys. Recognition of virulence determinants in this case relied on comparison of the vaccine virus with a neurovirulent revertant isolated from a vaccine recipient. It was concluded that two major attenuating mutations resided in the 5′ NTR (noncoding region) and in VP1.

A similar conclusion was derived from analysis of the type 3 vaccine strain, in which the wildtype (Leon) progenitor and a neurovirulent revertant from a patient were available for comparison. Remarkably, only 10 single-site mutations, resulting in four amino acid substitutions, differentiated the vaccine strain from its virulent progenitor. Two mutations, one located at site 472 in the 5′ NTR and the other a ts mutation in the VP3 region, contributed to the attenuation phenotype. Later, a third mutation located in the VP1 region was identified as an additional attenuating factor. The C→U mutation at 472 associated with the attenuated phenotype was observed to revert at high frequency following vaccination. Virus recovered from the gut of a human infant as early as 47 h after vaccination had reverted, and exhibited increased neurovirulence in monkeys. The role of mutation in the 5′ NTR region in attenuation was confirmed by mix-and-match type in vitro recombination experiments. Subsequently, mutations at positions 480 and 481 of poliovirus types 1 and 2, respectively, were similarly shown to be involved in the attenuation phenotype

(Figure 6). The 5′ NTR mutations locate at different bases in the same inferred secondary structure and may act by destabilizing this stem–loop structure, possibly affecting the translation efficiency of the viruses (Macadam et al. 1994). The other mutations affecting attenuation show no common features, and it is considered that 5′ NTR mutations may be responsible for the greater stability of the three Sabin live attenuated vaccines over their rivals. Similarly, a mutation in the 5′ noncoding region of coxsackie B3 virus has been identified as a determinant of cardiovirulence in mice (Tu et al. 1995).

It is likely for any virus that attenuation may be achieved by more than one route: for example, in the case of human respiratory syncytial virus (HRSV) mutations located in the *L* (polymerase) protein gene, the *F* (fusion) protein gene, or the start region of the *M2* protein gene, all have the potential to attenuate virulence. For this reason the most economical and reliable route to the identification of virulence factors, as exemplified in the case of the Sabin attenuated polioviruses, is to undertake a comparison of the genomic sequences of an existing empirically derived attenuated virus, its progenitor virulent parent, and, optimally, a revertant from the attenuated phenotype to a virulent phenotype. Once identified, critical attenuating mutations can be inserted into the genome of other strains of the same or closely related viruses by site-directed mutagenesis and recombinant virus rescued by recombination or reverse genetics according to the size and nature of the viral genome.

As in the case of the Sabin attenuated polioviruses, often remarkably few mutations distinguish virulent parental virus and attenuated progeny virus. Only 13 amino acid substitutions differentiated a candidate respiratory syncytial virus vaccine, derived semi-empirically by sequential selection of temperature-sensitive mutants under conditions of limiting mutagenesis, from its virulent parent. Comparison of the complete genome sequences of parental virus and first-, second-, and third-stage mutants, combined with testing in adult volunteers, enabled identification of a specific site in the respiratory syncytial virus polymerase protein gene that was a major determinant of attenuation (Tolley et al. 1996).

Attenuation by gene expression control

The location of a major attenuation determinant in the 5′ NTR region of poliovirus indicates that attenuation can be mediated at the level of control of mRNA synthesis, as the internal ribosome entry site of the poliovirus genome is located also in the 5′ region. In the case of nonsegmented negative-sense RNA viruses gene expression is controlled by the linear order of the individual genes and their relative distance from the single 3′-terminal transcriptional promoter. Thus the phenotypes of these viruses can be altered by gene rearrangement (Wertz et al. 1998; Ball et al. 1999) (Figure 7).

Flanagan et al. (2001) showed that rearrangement of the genes of vesicular stomatitis virus could eliminate clinical disease in swine, the natural host of the virus, thereby identifying an alternate route to attenuation (Figure 7b). Moving the nucleocapsid protein gene away from it normal location adjacent to the single transcriptional promoter site attenuated in stepwise fashion and finally eliminated the potential of the virus to produce disease in an experimental animal (Figure 7a). Combining this with relocation of the surface glycoprotein gene closer to the promoter site to increase its level of expression produced a virus that protected vaccinated animals against challenge with virulent virus of the same strain (Flanagan et al. 2000). Remarkably, these rearranged genomes could be propagated indefinitely and retained their altered phenotypes; some internal gene arrangements reduced viability, but others did not (Figure 7c). Subsequent work has shown that additional sequences can be inserted and retained in the genome of vesicular stomatitis virus, and that the level of expression of the supernumerary gene is determined by its relative position in the gene order (Wertz et al. 2002).

These results illustrate that negative strand viruses such as vesicular stomatitis virus, which are immune to disruption of gene order by recombination, can serve as stable gene vectors and vaccine delivery agents. The genome of vesicular stomatitis virus will tolerate a 40 percent increase in genome content (Haglund et al. 2002), allowing the insertion of heterologous antigens whose expression can be controlled by their position of insertion, and thereby increasing the scope of this approach to vaccine development. An unresolved question is why the majority of the nonsegmented negative-sense genome viruses (the order *Mononegavirales*) retain a common gene order, rather than any of the several viable permutations of the gene order.

Similar rearrangement of a strictly conserved genome organization without loss of viability has been observed also in the positive-sense RNA coronaviruses (de Haan et al. 2002).

Natural chimeras, transgenes, and genetically engineered vectors

In addition to the natural reassortants and recombinants of influenza viruses, rotaviruses, and picornaviruses encountered in nature, an expanding list of genetically engineered hybrid viruses is being described, e.g. Sindbis/VSV, influenza A/B, and VSV Indiana/VSV New Jersey, among others. The best-documented

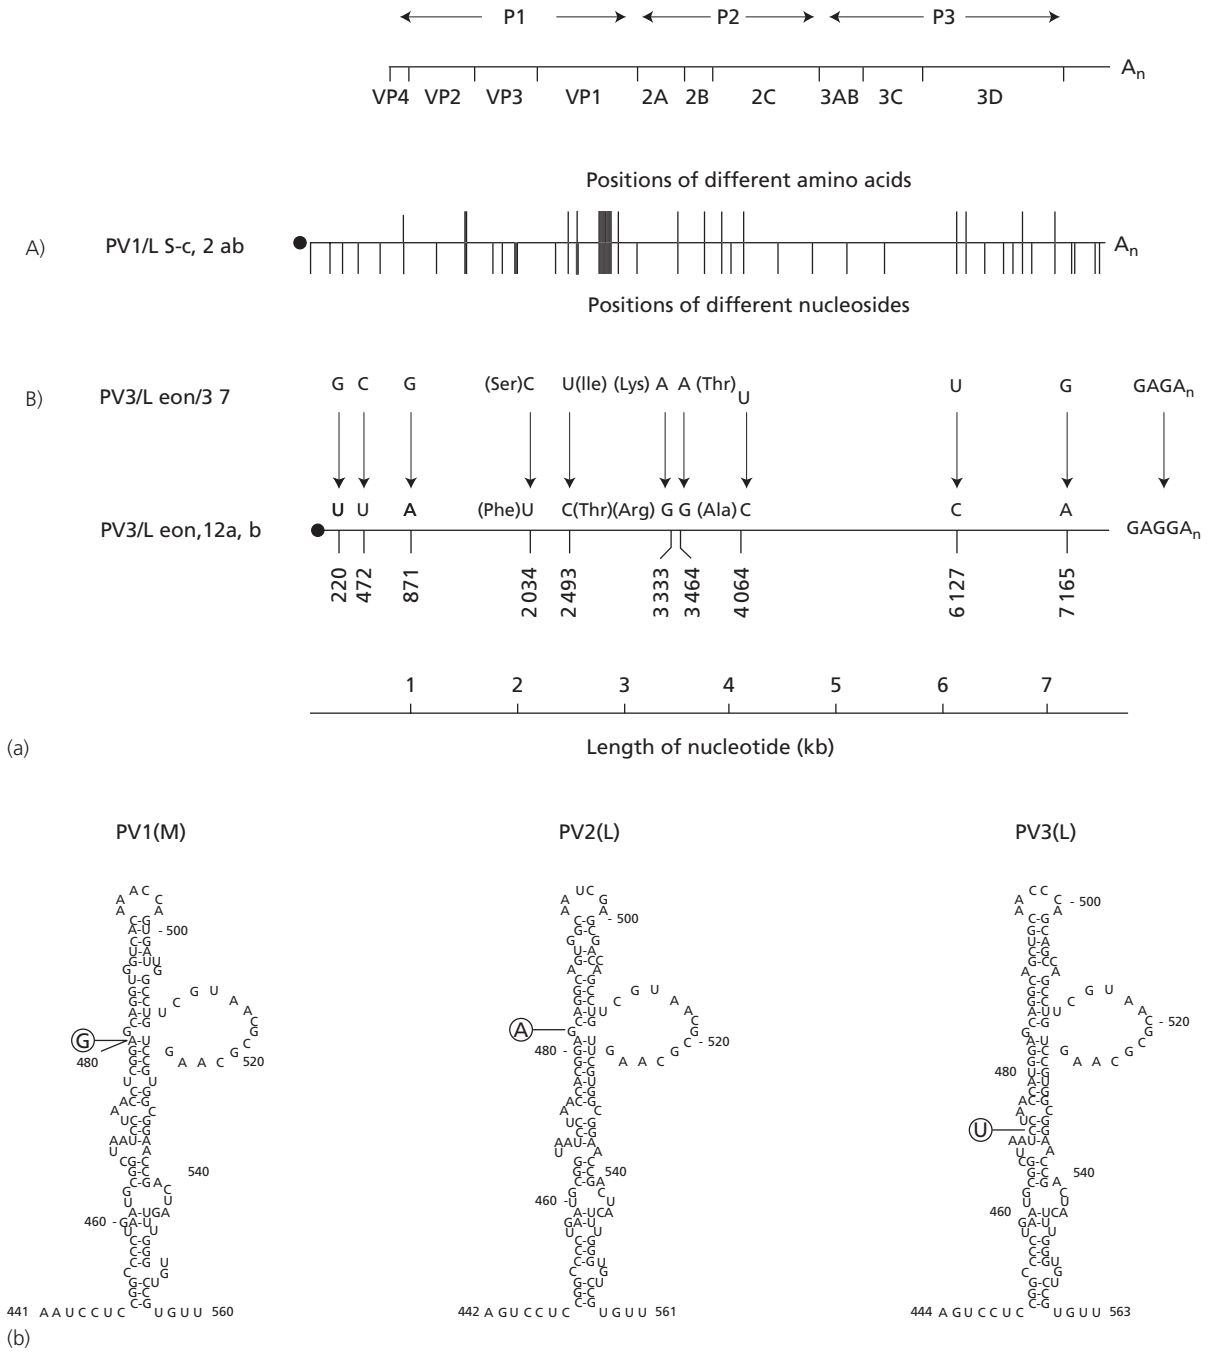

Figure 6 (a) *Location of attenuating mutations in the Sabin strains of poliovirus types 1 and 3: (A) the 21 amino acid and 56 nucleotide differences between the virulent parental (P1/Mahoney/41) and vaccine (P1/LSs, Zab) type 1 strains; (B) the four amino acid and ten nucleotide differences between virulent parental (P3/Leon/37) and vaccine (P3/Leon 12a1b) type 3 strains.* **(b)** *Domain V of the 5′ noncoding region of poliovirus types 1, 2, and 3. The attenuating mutations are circled. (Reproduced with permission from Almond 1987).*

chimeras are the adeno–SV40 hybrid viruses, which were inadvertently isolated during the 'adaptation' of adenovirus type 7 to growth in nonpermissive SV40-contaminated African green monkey kidney cells (Grodzicker 1981). Hybrid viruses were obtained in which adenovirus and SV40 virus genetic material was covalently linked. A few adeno–SV40 hybrids were isolated in which an intact adenovirus or SV40 genome was present, whereas others were incomplete and dependent for their existence on an adenovirus helper. Subsequently, helper-dependent and helper-independent adeno2–SV40 hybrids were produced in the same way. The ad2ND1 hybrid contained a nondefective, though incomplete, adenovirus genome covalently linked to

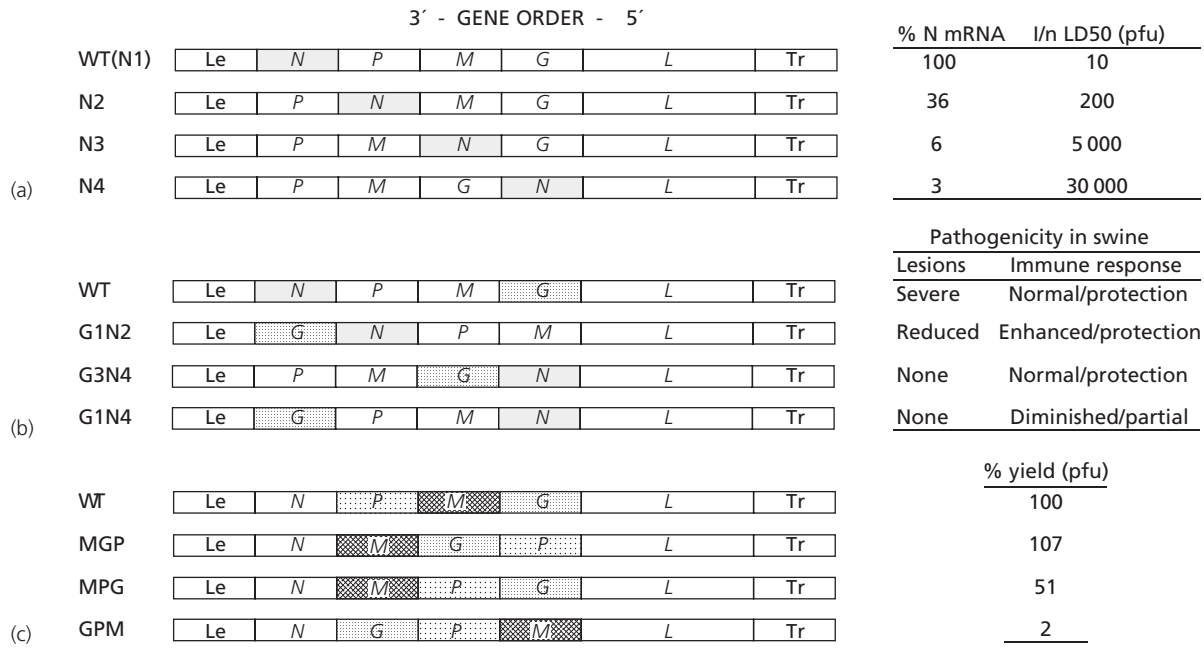

Figure 7 *Consequences of rearrangement of the gene order of vesicular stomatitis virus. The order of the components of the genome of vesicular stomatitis virus is indicated diagrammatically: the wildtype (WT) order is noncoding leader (Le), nucleocapsid* (N) *protein gene, phosphoprotein* (P) *gene, matrix* (M) *protein gene, glycoprotein* (G) *gene, polymerase* (L) *gene, and noncoding trailer (Tr) region. Panel* **(a)** *illustrates that translocation of the nucleoprotein gene down the gene order both attenuates transcription and reduces lethality for mice. Panel* **(b)** *indicates that translocation of the glycoprotein gene to a promoter-proximal position can enhance immunogenicity and eliminate clinical disease in the natural host of the virus. Panel* **(c)** *indicates that rearrangement of the internal genes can both enhance and reduce viability in cell culture.*

SV40 sequence. The SV40 sequence, which conferred the ability to multiply in monkey cells, varied from 7 to 43 percent, and the dispensable amount of adenovirus genome deleted varied from 4.5 to 7.6 percent. In all the adeno2–SV40 hybrids the insertion point was the same, namely at a site 14 percent from one end of the adenovirus genome.

Continuous passage of papovaviruses at high multiplicity of infection generates particles that have lower buoyant density than competent virions and contain less DNA. The DNA in these particles is circular and may have 10–50 percent of the papovavirus genome deleted. The segment deleted may be substituted by reiterated or nonreiterated host-cell DNA sequences, which may be larger than the segment deleted. These phenomena show that the genome of papovaviruses, and perhaps other DNA viruses, can be modified by the incorporation of host DNA sequences, and on rare occasions can contribute DNA sequences, either by homologous recombination or by illegitimate recombination, to other DNA-containing viruses.

An additional dimension has been added to genetic analysis by the ability to introduce foreign DNA into fertilized murine ova and to raise to maturity transgenic animals that have the foreign DNA integrated chromosomally. Among other things, this technique enables the determinants of tissue specificity to be investigated directly. For example, comparison of the pattern of tumor development in mice transgenic for genes from SV40, JC, and BK viruses indicated that tissue specificity is determined by early genes.

The construction of recombinant viruses for use as vaccines and gene vectors is probably the most obvious practical outlet for genetic technology. Vaccines of proven worth and safety (e.g. vaccinia virus, fowlpox virus, simian foamy virus, poliovirus, adenovirus, and others) can be employed as vectors for heterologous antigens. This approach to vaccine development (sometimes called vectored antigen delivery) has the advantages of inherent safety, speed, ease of administration and, in contrast to inactivated vaccines, the likelihood of obtaining a balanced cellular and humoral immune response. The potential limitation of pre-existing or induced immunity to the vector has not been a major problem in experimental trials. Control of rabies in wildlife by oral vaccination of red fox populations in Europe using a bait laced with a vaccinia virus/rabies *G protein* gene recombinant virus was the first successful application of this approach (Aubert et al. 1994).

Attenuated vesicular stomatitis viruses have been developed as vectors which can be delivered intranasally and support higher levels of expression than poxvirus vectors. In experimental animals these recombinants have proved effective in inducing humoral and cell-mediated responses to a variety of viral antigens (HIV gag and env; HCV E1 and E2; bovine viral diarrhea E2;

influenza A virus HA; rabbit papilloma virus L1; and respiratory syncytial virus G and F). Vesicular stomatitis vectors with the *G* (attachment) *protein* gene deleted (and expressing the influenza HA protein, or either G or F of respiratory syncytial virus) were protective and nonpathogenic in mice, and had the additional advantage of not inducing neutralizing antibodies to the vector itself (Kahn et al. 2001).

Gene therapy

Viruses have potential as efficient gene delivery vehicles in gene therapy, provided efficient transduction and sustained transgene expression can be achieved without compromising safety. Retroviruses and adenoassociated viruses are favored as gene delivery vehicles because of their low cytopathogenicity and/or tissue specificity. The strategies employed have ranged from complex to simple. The first successful treatment by gene therapy of a disease affecting multiorgan systems in a large mammal employed one of the simplest approaches. Mucopolysaccharidosis VII is a rare inherited disorder in dogs which manifests as ocular defects, cardiac disease, and bone abnormalities leading to loss of mobility by 6 months. This condition is due to a deficiency in the activity of the hepatic enzyme β-glucuronidase. Several 2–3-day-old dogs with this disorder received intravenous injections of Moloney murine leukemia virus carrying a normal canine *β-glucuronidase* gene under the control of a liver-specific promoter (Ponder et al. 2002). Transduced hepatocytes expanded clonally during normal liver growth and secreted normal levels of β-glucuronidase. Dogs treated in this way achieved normal body weight and were fully active at 17 months.

Molecular epidemiology

Recognition of genetic diversity through genome sequencing and phylogenetic analysis plays an increasingly important role in understanding the epidemiology of infectious disease. For example, a high proportion of patients with vaccine-related poliomyelitis exhibit vaccine-derived interserotype recombinant viruses that have also lost their attenuated phenotype (Cherkasova et al. 2002). Study of these isolates revealed a nonrandom distribution of synonymous mutations, conservation of secondary structural features, a relative dearth of mutations affecting the integrity of antigenic determinants, and a frequent occurrence of tripartite intertypic recombinants with either type 1 or type 3 homotypic genomic ends.

Analysis of all available complete genome sequences of dengue viruses revealed that about 10 percent were intrasubtype recombinants (Worobey et al. 1999), thereby discounting the use of partial genome sequences as markers for the whole genome. This phenomenon is a confounding factor in analysis of the circumstances that contribute to the appearance of the lethal hemorrhagic form of dengue fever. In the absence of recombination this complication does not arise. For example, a study of the genetic variability of human RSV, a virus initially assumed to be associated only with seasonal respiratory disease in infancy in temperate climates, established that RSV is a universal respiratory pathogen evolving in a global milieu. Isolates of RSV originating from many parts of the world could be fitted into a genotype classification defined by analysis of viruses recovered from the catchment area of a single hospital in a suburb of Birmingham (Cane and Pringle 1995).

The developing AIDS epidemic is one of the greatest challenges facing mankind. Phylogenetic analysis has established that the origin of the AIDS syndrome was not a unique event, and that the M, N, and O groups of HIV-1 have each arisen as a consequence of independnent zoonotic transmission of a simian immunodeficiency virus (SIVcpz) from a subspecies of the common chimpanzee (*Pan troglodytes troglodytes*) to humans. Other explanations for the origin of the M, H, and O groups of HIV-1, such as viral diversification within human populations, are inconsistent with existing phylogenetic data (Gao et al. 1999). The closest relatives of HIV-2 have been found in the sooty mangabey (*Cerocebus atys*), and again phylogenetic evidence suggests independent transmissions to humans. A recent survey has established that a substantial proportion of wild monkeys in West Africa are infected with a diversity of simian immunodeficiency viruses, serologically related to HIV to varying extents, representing a reservoir of potential human pathogens. The emergence of the lentivirus immunodeficiency diseases in humans has been correlated with the increased hunting of primates to provide meat for human consumption (Peeters et al. 2002). On the other hand, a putative evolutionary link has been proposed between HIV-1 and a group of endogenous retroviruses (HERV-K) that are present at about 50 proviral copies per haploid genome and which entered the human genome some 30 million years ago. The connection is based on identification of a functional homolog of the HIV-1 Rev protein encoded in the HERV-K genome, and the presence of a target RNA sequence in the HERV-K LTR region recognized by HIV-1 Rev (Yang et al. 1999), perhaps indicative of previous human encounters with such retroviruses.

Immune evasion

Characterization of the genomes of the large DNA viruses has identified a number of genes that interfere with the immune response of the host. The genome of vaccinia virus comprises about 200 genes, about one-third of which are dispensable for propagation of the

virus in cultured cells. These apparently dispensable genes map in the extensive dispensable terminal regions of the vaccinia virus genome, together with host range and virulence markers. Some of these dispensable genes seem to contribute to the survival of the virus in vivo by interfering with specific arms of the immune system, such as complement, interferon, inflammation, cytokines, and cytotoxic T-lymphocyte recognition. The vaccinia virus genome encodes several proteins that have amino acid similarity to components of the complement system, and may prevent complement activation by competitively binding either complement control factors or complement receptors. Analogous genes are present in some herpesviruses.

At least four poxvirus genes interfere with interferon action. However, interference with the interferon response is not restricted to the large genome DNA viruses. Negative-sense RNA viruses also encode proteins that interfere with the interferon response. For example, the *NSs* gene product of bunyamwera virus, identified as a nonessential protein modulating pathogenesis, functions as an interferon induction antagonist to enhance virulence (Weber et al. 2002). Similarly, by construction of deletion mutant and recombinant viruses by reverse genetics it has been established unequivocally that the promoter-proximal *NS1* and *NS2* genes of pneumoviruses, two abundantly transcribed genes of previously unknown function, function as α/β-interferon induction antagonists (Bossert and Konzelmann 2002). Other paramyxoviruses have evolved different mechanisms for counteracting the cellular interferon response. Sendai virus, SV5, and human parainfluenza virus 3 block both type I and type II inferferon responses by targeting the cellular signaling factors (STAT 1 and STAT 2) involved in interferon signaling, an effect which is mediated by one of the alternate products expressed from the virus phosphoprotein gene (Andrejeva et al. 2002).

These are some examples of the continuing value of application of genetic methodology in both fundamental and applied virology.

INTRODUCTION

As obligate intracellular parasites, viruses depend on their host cells at all stages of their infectious cycles. Different viruses impinge on almost every aspect of host-cell metabolism, so virus–host cell interactions are diverse and complex. The details of these interactions have been shaped during the co-evolution of individual viruses and their hosts, and they can be fully understood only within that context. In fact, examination of the defenses mounted by cells and organisms against viral infection, and of the various mechanisms that different viruses have evolved to help them evade these defenses, provides a revealing glimpse into the heart of the host–parasite relationship (Smith 1994).

Experimental studies of virus–cell interactions are usually performed in cell culture, by using purified viruses to infect cultured cells that may be a different type or even a different species from those in which the viruses evolved. Because the consequences of infection can vary greatly from one cell type to another, the link between laboratory studies of virus–cell interactions and the behavior of viruses in their natural state is sometimes tenuous. Nevertheless, experimental studies of virus–host cell interactions have not only enriched our understanding of viral infection but also illuminated many areas of molecular and cellular biology. Among these areas are the mechanisms of receptor function (Nomoto 1992; Haywood 1994; Wimmer 1994) and membrane fusion (White 1992; Bentz 1993; Earp et al. 2005); the pathways and control of macromolecular synthesis, processing, and transport (Nevins 1989; Ehrenfeld 1993; Gebauer and Hentze 2004); the regulation of cell cycling (Levine 1993; Weinberg 1995); and oncogenic transformation (Teich 1991; Jansen-Durr 1996). This chapter presents a survey of this complex and far-reaching subject, and refers the reader to more detailed coverage of specific topics in other chapters. It also contains an extensive bibliography that includes many review articles to guide those interested in reading further.

Cytopathic effects of viral infection

Infection of susceptible cells with an animal virus usually causes cytological changes that are visible by light microscopy and collectively referred to as the cytopathic effect (CPE) of the virus. The nature of the CPE differs between viruses and from one type of virus–cell interaction to another (described in Types of virus–host cell interactions). In the case of a cytocidal virus infecting a cell monolayer, for example, the CPE frequently includes cell rounding and loss of adherence to the tissue-culture plate, visible consequences of the perturbations of cellular metabolism that presage the death of the cell (Figure 1a). In contrast, cells infected with a tumor virus, where the outcome is not cell death but neoplastic transformation, undergo more subtle changes in morphology, although the overall consequences of infection both in cell culture and in animals can be at least as profound (Figure 1c).

Viral CPEs are not due simply to the increased load on cellular protein synthesis (which is usually insignificant)

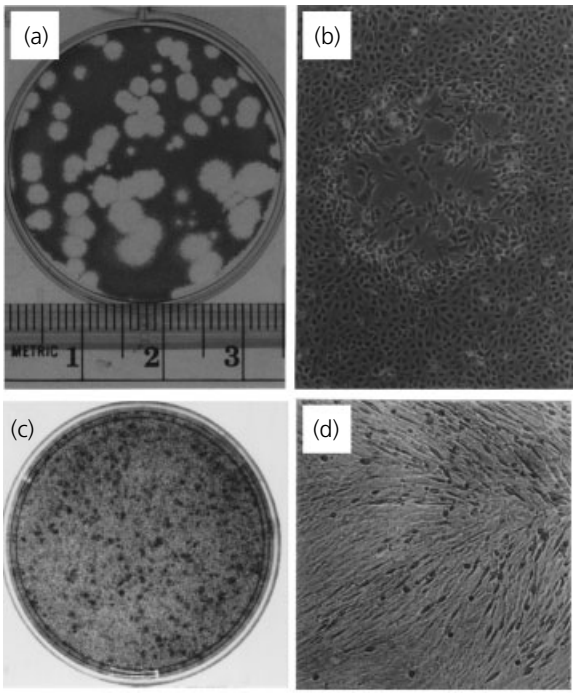

Figure 1 (a) *Plaque assay of a lytic virus (vesicular stomatitis virus).* **(b)** *Microphotograph of the typical cytopathic effect (CPE) of a lytic virus (vaccinia virus).* **(c)** *Focus-forming assay of a transforming retrovirus.* **(d)** *Microphotograph of part of a focus of transformed cells. nor even to its inhibition, because translation in uninfected cells can be blocked by drugs without inducing a CPE. On the contrary, some aspects of viral CPEs are directly due to the action of specific viral proteins: for example, detachment of adenovirus-infected cells from cell-culture plates results from the penton-base protein of the virion binding to cellular integrins during entry and thereby disrupting their interaction with vitronectin that was responsible for cellular adherence (Wickham et al. 1993). Similarly, some retroviral proteases cause cell rounding by disrupting the cytoskeleton (Luftig and Lupo 1994). However, it also seems that cells can respond to viral infection by launching a specific genetic program that leads to cell death (see Apoptosis), which indicates that some of the consequences of infection are self-inflicted (Razvi and Welsh 1995; Steller 1995; Everett and McFadden 1999). The benefit to the organism of thus limiting the spread of infection outweighs the cost in sacrificed cells (Williams 1994).

QUANTITATIVE ASPECTS OF VIRUS–CELL INTERACTIONS

Multiplicity of infection

Infection is an encounter between two populations: the virus particles and the host cells. The average number of infectious virus particles per cell is called the multiplicity of infection (MOI). When the MOI is very low (10^{-4}, say), only a correspondingly small fraction of the cell population will be infected initially, although the infection can then spread through the cell culture as the virus multiplies. If the spread is contained, by an agarose overlay for example, areas of infected cells (plaques) will develop around each initial infection site, allowing the number of infectious particles (or plaque-forming units (pfu)) in the virus inoculum to be calculated. This is the basis of the plaque assay, an example of which is shown in Figure 1a,b. In contrast, when the MOI is high, essentially all the cells will be infected at the outset and the virus will be limited to a single round of synchronous replication. Tumor viruses, which transform cells rather than killing them, produce local foci of transformed cells in culture (Figure 1c,d) and can therefore be quantified by an analogous assay that measures the number of infectious particles (or focus-forming units (ffu)) in a tumor virus preparation.

Poisson distribution

The distribution of virus particles among a population of cultured cells is random and can be described mathematically by the Poisson distribution. This formula relates the average MOI (m) to the fraction of cells (P) that actually receive any given number (k) of infectious particles. It shows that an MOI of 1.0 pfu per cell will result in the infection of only 63.2 percent of the population, and that an MOI of $\geqslant 5$ is required to infect at least 99 percent of the cells (Table 1).

Ratios of physical particles to plaque-forming units

Not all virus particles in a preparation are capable of forming a plaque; indeed, the particle:pfu ratios for most animal viruses are seldom lower than 10 and sometimes much higher. There are several explanations for this surprising and often overlooked result. First, infection is a multistep process in which the probability of successful completion of each step may be less than 100 percent even for an intrinsically infectious particle. Secondly, the apparent homogeneity of a virus preparation can conceal a substantial level of microheterogeneity: differences in the age of individual particles, their protein composition, and even their genome sequences can influence infectivity. Among the RNA viruses, the high polymerase error rate that results from the absence of proofreading during RNA replication creates a population of genomes whose sequences compose a molecular swarm or quasi-species distribution around a consensus sequence (Smith and Inglis 1987; Holland et al. 1992; Drake 1993; Eigen 1993; Duarte et al. 1994; Domingo and Holland 1997). This concept has profound

Table 1 *Poisson distribution: percentage of cells receiving 0, 1, and >1 particles at different MOIs*

Multiplicity of infection (pfu/cell)	Uninfected cells (%)	Singly infected cells (%)	Multiply infected cells (%)
0.0	100.0	0.0	0.0
0.5	60.7	30.3	9.0
1.0	36.8	36.8	26.4
2.0	13.5	27.0	59.5
3.0	5.0	15.0	80.0
5.0	0.67	3.35	96.0
10.0	0.0045	0.045	99.95
$P(k) = (e^{-m}.m^{k}).I/k!$			
$P(0) = e^{-m}$			
$P(1) = m.e^{-m}$			
$P(>1) = 1-e^{-m}(m+1)$			

implications for our understanding of RNA virus evolution (The origin and evolution of viruses).

Noninfectious virions can nevertheless participate in infection under both natural and experimental conditions. Typically, the number of particles that can undergo receptor binding and other early stages of infection will far exceed the infectious titer, a fact that complicates the study of early events in virus–cell interaction because it is difficult to identify the minority of particles that are on the pathway to productive infection (Wilson 1992). In many cases the genomes of noninfectious particles can engage in complementation and recombination with one another and thus contribute to the outcome of infection. Moreover, some of the most important physiological effects of infection, such as killing of the host cell and the induction of interferon (see Induction and actions of interferons and The role of cytokines in viral infections), do not depend on the production of viral progeny and can therefore be accomplished by more virus particles than are needed to demonstrate full infectivity (Marcus and Sekellick 1974). The situation is further complicated by the fact that most animal viruses generate defective particles, particularly on repeated passage at high MOI. As their name implies, defective particles are incapable of replication except when supported by coinfection with their parent virus with which they often interfere, thus earning the name defective interfering (DI) particles. Under experimental conditions DI particles can play critical roles in maintaining persistent infections, modulating viral pathogenesis (Pathogenesis of viral infections), and guiding virus evolution (The origin and evolution of viruses), and it seems likely that they exert similar effects in nature (Dimmock 1985; Barrett and Dimmock 1986; Whitaker-Dowling and Youngner 1987; Roux et al. 1991; Bangham and Kirkwood 1993).

Single-hit relationships

The fact that preparations of animal viruses have high particle:pfu ratios does not mean that more than one particle per cell is required to initiate a productive infection. The quantitative relationship between virus inoculum and infectivity is generally linear rather than exponential, which shows that infection is a single-hit phenomenon. Combining this observation with a demonstration that the inoculum contains only monomeric virus particles proves that under normal conditions a single virion suffices to infect a cell, although infections that depend on complementation or recombination between viral mutants provide exceptions to this rule. For viruses that have naturally segmented genomes, the quantitative dependence of infectivity on inoculum can supply information on the distribution of genome segments among the individual virus particles.

TYPES OF VIRUS–HOST CELL INTERACTIONS

Viral infections fall into two categories, productive and nonproductive, depending on whether or not viral progeny are produced from the infected cells (Table 2). In reality, cellular permissiveness covers a wide spectrum from total nonproductivity, through cases where very low numbers of virions are released, to fully productive situations in which each cell makes hundreds or thousands of infectious particles. Moreover, in the case of latent infections in animals (e.g. by members of the herpesvirus family), infectious virus can re-emerge several years after a nonproductive interaction in one cell type as a fully productive infection in another (Herpesviruses: general properties and Alphaherpesviruses: herpes simplex and varicella-zoster). As far as the host cell is concerned, its survival is determined not simply by whether the infection is productive, but by the interplay between its genetic program and that of the virus, as described in Cellular responses to viral infection (and see Table 2).

Productive infections

The steps in a typical productive viral infection are as follows:

Table 2 *Classification of virus–cell interactions*

Consequences for the:				
Virus	**Cell**	**Classification**	**Specific example**	**Chapter**
Productive	Lethal	Cytolysis	Poliovirus in human cells	40
	Nonlethal	Transformation	Rous sarcoma virus in chicken cells	58
		Persistence	Lymphocytic choriomeningitis virus in mouse cells	49
Nonproductive	Lethal	Apoptosis	Vaccinia virus in Chinese hamster ovary cells	30
	Non lethal	Transformation	Simian virus 40 in mouse cells	24
		Latency	Herpes simplex virus in neural cells	26

1 adsorption of the virus to specific cellular receptors;
2 its penetration across the plasma membrane and into the cell;
3 virus disassembly resulting in partial or complete uncoating of its genome;
4 transcription, translation, and replication of the viral nucleic acid (the order and subcellular location of these steps reflecting the genome strategy of the family to which the virus belongs);
5 assembly of progeny virus particles;
6 their release from the cell.

CYTOCIDAL INFECTIONS

Whether these events kill the host cell depends on the type of virus. For a typical, nonenveloped, cytocidal virus such as poliovirus (Picornaviruses) which is released when the cell membrane disintegrates, cell death coincides with virus release, although some lytic viruses may be released by an unknown mechanism before the cells burst (Tucker and Compans 1993). In contrast, the release of cytocidal enveloped viruses such as vesicular stomatitis virus (VSV) (see Rhabdoviruses: rabies), which mature by budding, occurs in a more prolonged manner and precedes the death of the host cell.

PRODUCTIVE TRANSFORMATION

This ability of enveloped viruses to bud from cells without necessarily killing them is exploited by the RNA tumor viruses (Prions of humans and animals), which establish productive infections in which the host cells undergo neoplastic transformation rather than death (Viral oncogenicity). By integrating their entire genome into that of the host cell and expressing oncogenes, RNA tumor viruses transform cells to a state of uncontrolled cell division and continuous release of infectious viral progeny.

PERSISTENCE

Persistent infections in cell culture provide situations that are intermediate between these two extremes, and several mechanisms of persistence have been identified (de la Torre and Oldstone 1996). These include carrier cultures, in which for some reason only a specific subpopulation of cells is susceptible to infection; cases in which virus spread is restricted because it can occur only by cell-to-cell contact; and steady states in which infected cells coexist with the virus because they have similar rates of multiplication. In cell culture, temperature-sensitive mutants, DI particles, and interferon have all been implicated in maintaining persistence; the situation in animals is even more complex because it also involves interactions with different cell types, cytokines, and the immune system (Oldstone 1991; Levine et al. 1994; ter Meulen 1994). These aspects are described in detail elsewhere (The immune response to viral infections and The role of cytokines in viral infections).

Nonproductive infections

Counterintuitively, nonproductive infections are often more challenging than productive ones, both intellectually and medically. In cells that carry receptors for a virus, the initial stages of a nonproductive infection are the same as those listed above for productive situations: receptor binding, penetration, and uncoating. In contrast, cells that lack appropriate receptors are usually not susceptible to infection, although some exceptions to this rule are described in Antibody-mediated enhancement. After these initial stages, however, nonproductive infections can have several different causes, courses, and consequences (see Table 2).

APOPTOSIS

In some cases, the early steps of infection trigger the onset of the cell's apoptotic response, resulting in prompt cell death without either virus replication or the production of progeny (Razvi and Welsh 1995; Roulston et al. 1999). Infection of Chinese hamster ovary cells by vaccinia virus provides a good example of this. Several viral genes have been identified whose actions delay the onset of apoptosis (White 1993; Clem and Miller 1994; Ink et al. 1995; Benedict et al. 2002), which suggests that anti-apoptotic mechanisms may be widespread among animal viruses.

NONPRODUCTIVE TRANSFORMATION

Replication of the smaller DNA viruses such as those in the polyoma- and papilloma virus families (

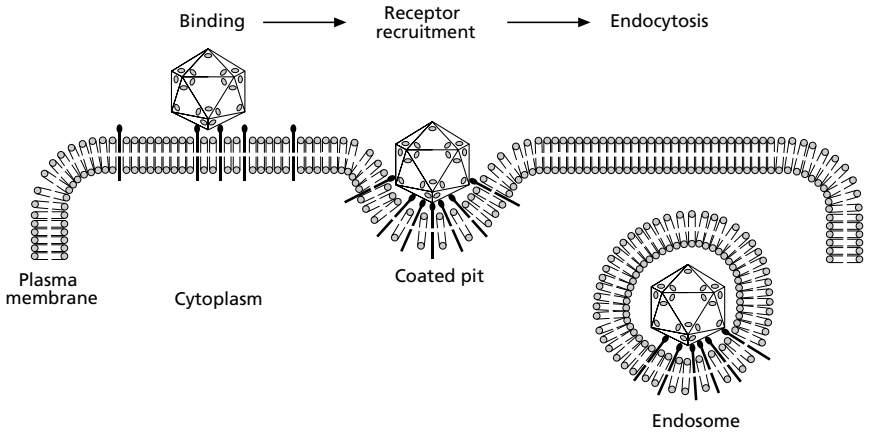

Figure 2 *Receptor-mediated endocytic uptake of a virus particle*

The origin and evolution of viruses) depends on viral oncogenes that coax the infected cell into the S phase of the cell cycle and thus establish conditions that are conducive for DNA synthesis. This is particularly critical for papillomaviruses, which replicate only in terminally differentiated, noncycling cells of the epidermis. In this situation, any block in virus replication that allows the cell to survive the infection can lead to integration of the viral oncogenes and consequent neoplastic transformation of the cell (see Table 2).

LATENCY

Of all the types of virus–host interactions, those that result in latency are the most perplexing (Garcia-Blanco and Cullen 1991). Members of the alphaherpesvirus family (Alphaherpesviruses: herpes simplex and varicella-zoster) typically progress from primary productive interactions, often with epithelial cells, to secondary latent infections, usually in neural cells, from which they can re-emerge periodically throughout the life of the infected individual (Wagner 1994). The viral genome remains intact during latency and is maintained as an episome in the nucleus, with at most a small subset of the viral genes being expressed. This situation is best understood for latent infections established by Epstein–Barr virus in B lymphocytes (Masucci and Ernberg 1994; Farrell 1995; Rowe 1999), which can be examined in cell culture. The general mechanisms by which herpesviruses establish, maintain and re-emerge from latency are subjects of intense investigation, but the scarcity of cell culture systems in which these processes can be duplicated renders them difficult to study.

ADSORPTION OF VIRUSES TO HOST CELLS

The first step in virus–cell interaction is a specific noncovalent binding between attachment sites on the surface of the virion and receptors on the plasma membrane of the host cell. Unlike some bacteriophages, all animal viruses carry multiple copies of their attachment proteins or sites, usually arranged in symmetrical or regular arrays on the surface of the virion (The morphology and structure of viruses). Even the small picornaviruses have 60 receptor-binding sites per virion, and influenza virus has several hundred. What fraction of these sites must be occupied for successful virus binding and uptake is unknown, although it is probably much less than 100 percent and may vary widely among different viruses. Indeed, a current model for the early stages of virus uptake proposes that the initial interaction with one or a few receptor molecules is followed by the recruitment of more receptors that can diffuse laterally in the plasma membrane. This would strengthen the binding, cause invagination of the membrane around the virus particle, and initiate what used to be called 'viropexis,' but is now generally referred to as 'receptor-mediated endocytosis' (Figure 2). See Wimmer (1994) for several reviews on all aspects of this subject.

The receptor–virus interaction can fulfil two distinct functions: positioning the virus particle for uptake by the cell and, at least in some cases, promoting virion disassembly. Virus structures have evolved to serve as metastable intermediates between successive cycles of replication, and some receptors not only bind the incoming virus particle but also act as keys to unlock its structure (see Consequences of receptor binding). Of course, the presence of cell surface components that can perform these functions is not due to natural selection of cells for their ability to be infected, but rather to opportunism by viruses whose potential for faster evolution allows them to take advantage of existing host cell molecules with other functions. A remarkable variety of cell surface molecules have been co-opted by different viruses to enable them to bind and enter cells (Table 3), and these receptors are described further in the section entitled Cellular receptors for viruses.

Table 3 *Some examples of virus receptors*

Virus family	Viruses	Receptors
Coronaviridae	*Murine hepatitis virus*	Carcinoembryonic antigen family member
	Human coronavirus 229E	Aminopeptidase *N*
	Human coronavirus OC43	*N*-acetyl-9-*O*-acetylneuraminic acid
Herpesviridae	Epstein–Barr virus	B lymphocyte C3d complement receptor (CD21)
	Herpes simplex virus	Heparan sulphate moieties of proteoglycans
Orthomyxoviridae	*Influenza A and B viruses*	*N*-acetylneuraminic acid (sialic acid) on glycoproteins and glycolipids
	Influenza C virus	*N*-acetyl-9-*O*-acetylneuraminic acid
Paramyxoviridae	*Sendai virus*	Sialoglycoprotein GP2
	Measles virus	Complement regulator CD46 and SLAM
Picornaviridae	*Poliovirus*	Poliovirus receptor (immunoglobulin superfamily member)
	Rhinoviruses (major group)	Intercellular adhesion molecule 1 (ICAM-1)
	Rhinoviruses (minor group)	LDL receptor
	Foot-and-mouth disease virus	Integrin (RGD-binding protein)
Reoviridae	Reovirus type 3	β-Adrenergic receptor
Retroviridae	*Human immunodeficiency viruses*	T-cell surface glycoprotein CD4, galactosyl ceramide, and chemokine co-receptors
	Ectropic murine leukemia virus	Cationic amino acid transporter
	Gibbon ape leukemia virus	Sodium-dependent phosphate symporter
	Feline leukemia virus	Sodium-dependent phosphate symporter
Rhabdoviridae	Vesicular stomatitis virus	Phosphatidylserine and phosphatidylinositol
Togaviridae	*Sindbis virus*	High-affinity laminin receptor

For references to the original work that described these receptors, see Lentz (1990), Haywood (1994), and Wimmer (1994).

The presence of an appropriate receptor is usually necessary but not always sufficient to allow a particular virus to infect a cell or organism. For example, poliovirus naturally infects only humans and closely related primates because certain cells of these species have a receptor (the poliovirus receptor (PVR)) to which the virus can attach, but the host range of the virus can be extended to mice if they are engineered to express the human gene for PVR (Ren et al. 1990; Nomoto et al. 1994). In contrast, mouse cells expressing CD4, the receptor for human immunodeficiency virus (HIV), can bind the virus but are not infected by it, showing that in some cases there is more to uptake and penetration than simple binding (see Entry accessory factors). Similarly, although receptor distribution is a major determinant of viral tissue tropism, the susceptibility of different tissues in an organism does not simply reflect the tissue distribution of the receptor, because productive infection often requires accessory factors for virus entry (Entry accessory factors), as well as a hospitable intracellular environment for replication. The overall relationship between viral entry mechanisms examined in cell culture and virus spread during a natural infection is a difficult and contentious area of virology.

Viral attachment proteins and sites

In the simplest cases, the task of binding to the host cell has been assigned by evolution to a single species of viral surface protein, such as the hemagglutinin (HA) of influenza virus (Weis et al. 1988) or gp120 of HIV (Weiss 1992), although such attachment proteins usually function as oligomers. In more complex situations such as the picornaviruses, receptor-binding sites on the virion surface are created at the interfaces between two or more viral polypeptides (Colonno 1992; Olson et al. 1993). Larger viruses may show a still higher level of complexity, in which two or more viral surface proteins are involved in a series of progressively tighter interactions with different cell surface components. For example, glycoprotein C of herpes simplex virus (HSV) binds the abundant heparan sulfate moieties of cell surface proteoglycans whereas glycoprotein D binds to mannose-6-phosphate receptors (Spear 1993; Brunetti et al. 1994). Strictly speaking, such downstream components of a multistep entry pathway are best considered 'entry accessory factors' (Entry accessory factors) rather than viral receptors. Nevertheless, the idea of a rapid, relatively low-affinity interaction being followed by a slower, tighter binding, either to a secondary component or to newly recruited primary receptors, is reminiscent of the mechanism by which circulating leukocytes adhere to vascular endothelial cells, by rolling across weak receptors (selectins) before binding irreversibly to integrins (Lawrence and Springer 1991). The speed of the initial binding in three dimensions that is required to capture a passing particle is combined with a slower, two-dimensional search for the interactions that give the overall process its necessary high affinity.

GLYCOPROTEIN SPIKES

Many enveloped viruses display their attachment proteins as surface spikes that project perpendicularly from the viral envelope. These spikes are visible in electron micrographs and consist of oligomers of virus-specified integral membrane glycoproteins. In some, perhaps many, cases, the arrangement of the surface spikes reflects the symmetry of the nucleocapsid underlying the viral envelope (Paredes et al. 1993; Cheng et al. 1995). The three-dimensional structure of one viral attachment glycoprotein, the influenza virus HA, was determined at near-atomic resolution in 1981 and has been influential in shaping ideas of the structure and function of such proteins (Figure 3) (Wiley and Skehel 1987). It consists of a bundle of three identical monomers extending 135 Å from the surface of the viral envelope, arranged around a symmetry axis that is parallel to its length. Each monomer contains two disulfide-linked polypeptides, HA1 and HA2, produced by cleavage of the 550 amino acid primary translation product. The globular top of the trimeric bundle has three concave binding sites for sialic acid, the cellular receptor for influenza virus, as well as several antigenic sites that elicit and react with antibodies that neutralize the infectivity of the virus. At its bottom, HA2 anchors the protein by passing through the viral membrane, although the protein whose structure was determined was first made soluble by removal of the transmembrane domain.

A very different picture is presented by glycoprotein E of the flavivirus tick-borne encephalitis virus (TBEV) (Flaviviruses) (Rey et al. 1995). Like influenza virus HA, this is a type I integral membrane protein that is anchored in the viral envelope by its C terminus. However, rather than forming a protruding spike, the TBEV glycoprotein forms an elongated homodimer that lies flat on the surface of the viral envelope with a symmetry axis that is perpendicular to its length (Figure 4). The receptor-binding domain has an immunoglobulin-like folded structure that presents the binding site on the surface of the virion.

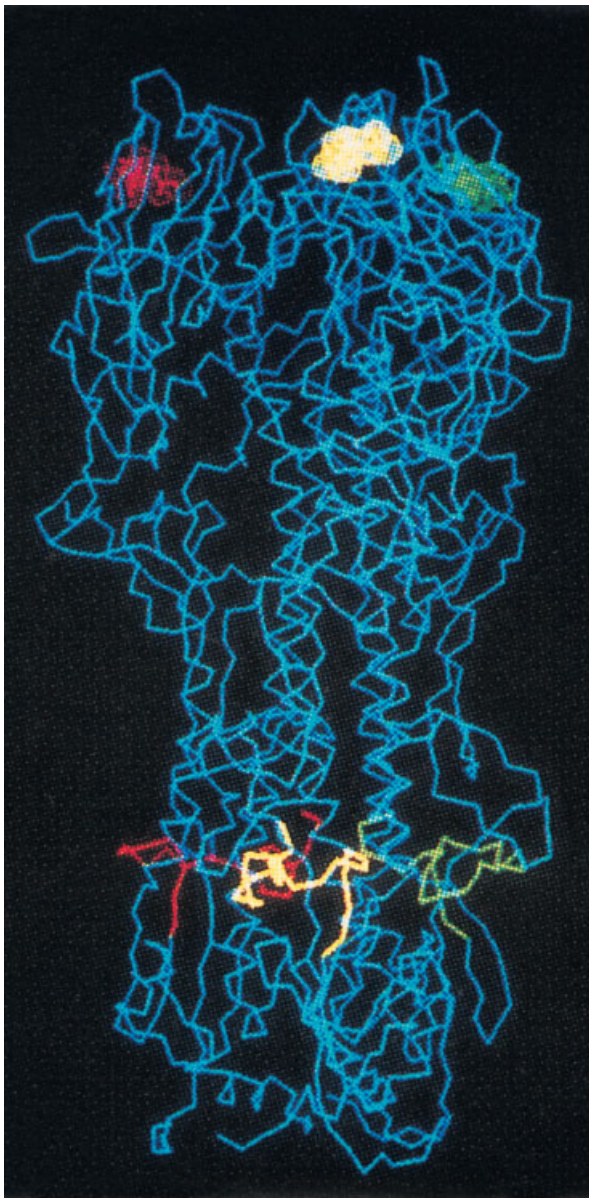

Figure 3 *The influenza virus hemagglutinin (HA). The α-carbon backbone of the HA trimer is displayed in blue with the three fusion peptides, located in the stem of the molecule, highlighted in red, yellow, and green. The molecular surfaces of three sialic acid residues are shown (red, yellow, green) in the receptor-binding sites of the globular head domains. The three monomers would be anchored in the viral membrane at the bottom (from White (1992)).*

CAPSID ATTACHMENT SITES

In nonenveloped viruses, the receptor-binding sites are built into the architecture of the particles and are thus displayed in a symmetry determined by that of the capsid. A technical consequence of this is that individual virus particles with receptors bound at each site can be visualized using cryo-electron microscopy and image reconstruction methods to achieve a resolution of about 25 Å. Figure 5a shows a rhinovirus particle decorated with its receptor, intercellular adhesion molecule 1 (ICAM-1) (Olson et al. 1993; Rossmann et al. 1994). Sixty receptor molecules are bound to each virion, arranged in groups of five around each of the 12 axes of five-fold symmetry in the icosahedral particle. The receptors thus occupy chemically identical binding sites which, in this and some other picornaviruses, lie in a trenchlike depression called the canyon that encircles each fivefold axis. A higher resolution image that shows how a single receptor molecule fits into the canyon has been generated by combining the crystal structure of the rhinovirus particle with the predicted structure of ICAM-1 (Figure 5b). It shows that the binding site is created and protected by the juxtaposition of the capsid proteins VP1, VP2, and VP3, parts of which form the

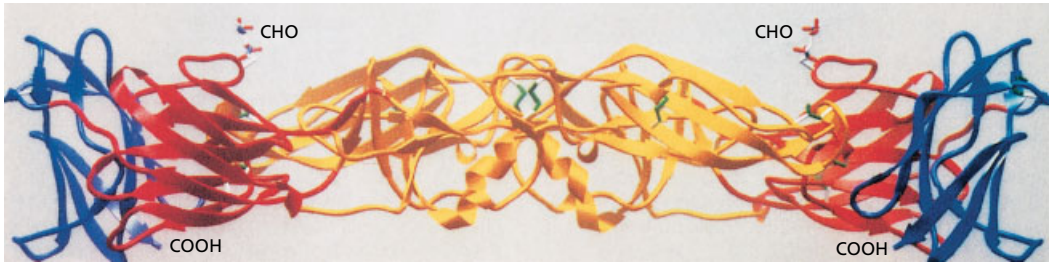

Figure 4 *Three-dimensional structure of glycoprotein E of tick-borne encephalitis virus. The dimer is viewed from the side, as it would lie on the surface of the viral membrane (from Rey et al. (1995)).*

walls of the canyon. Ultimately, it may prove possible to co-crystallize a virus–receptor protein complex and directly examine the molecular contacts at atomic resolution.

The specific contacts by which a viral attachment protein binds to its receptor, and hence the amino acid residues involved, are largely fixed by the requirement that they must create a binding surface with steric, electronic, and hydropathic complementarity for the receptor. It is important, therefore, that these residues avoid immune surveillance, because an antibody directed specifically and exclusively against the receptor-binding site would create a barrier to infection that the virus could not circumvent by mutation. This problem has been solved in different ways by different viruses (Chapman and Rossmann 1993). For example, location of the receptor-binding sites in the canyon of rhino- and polioviruses protects them from reach by antibodies which are much bulkier than the receptors (Rossmann 1989). In contrast, the receptor-binding site in foot-and-mouth disease virus is in a surface loop that may avoid antigenic scrutiny by being structurally mobile. Finally, there may be cases where the receptor-binding site mimics the structure of the natural ligand so precisely that the immune system does not recognize it as foreign.

Cellular receptors for viruses

A wide variety of cell surface molecules can be used as receptors by different viruses (Table 3). In some cases, a ubiquitous carbohydrate modification is recognized, such as sialic acid or heparan sulfate on a glycoprotein or glycolipid, whereas in other cases it is a specific protein that may be present on the surface of only certain cell types (such as CD4 on T lymphocytes), which thus directs and restricts the tropism of the virus (Lentz 1990; Wimmer 1994). The receptors for poliovirus (PVR), rhinovirus (ICAM-1), and HIV (CD4), among others, belong to the immunoglobulin superfamily of proteins, and contain three to five repeats of the 'immunoglobulin fold,' a structural domain that is characteristic of the immunoglobulins (White and Littman 1989). The three-dimensional structure of two such domains in a fragment of CD4 that includes the HIV-binding site is illustrated in Figure 6 (Harrison et al. 1992; Signoret et al. 1993). Since members of this protein superfamily have been naturally selected for cell surface expression and the ability to bind protein ligands with high specificity, it is easy to understand why they should have been commandeered as viral receptors. Indeed, two very different viruses, HIV and human herpesvirus 7, both use CD4 as their receptor, and the malaria parasite also uses ICAM-1 for cell attachment. The versatility of the immunoglobulin fold as a protein-binding domain is further illustrated by the fact that it sometimes occurs in the other partner in the interaction, the viral attachment protein (Rey et al. 1995).

Just as dissimilar viruses can share the same receptor, so can closely related viruses use different receptors. Human rhinoviruses, of which there are over 100 serotypes, divide into a major group that use ICAM-1 and a minor group that use the low density lipoprotein (LDL) receptor. In this case, the use of different receptors does not seem to influence the outcome of infection, but there are examples where the use of alternative receptors by a single virus can have profound consequences. The ability of HIV to use galactosyl ceramide instead of CD4 to enter cells may be responsible for its infection of the brain and the resulting acquired immunodeficiency syndrome (AIDS)-related dementia (Weiss 1992).

Infection of animals is usually initiated in epithelial cells, which are naturally polarized and express different sets of proteins on their apical and basolateral surfaces (Tucker and Compans 1993; Eaton and Simons 1995). Interaction of viruses with polarized cells whose receptors are distributed asymmetrically can occur only at the cell surface that expresses the receptor, because the intercellular tight junctions prevent access of the virus to the other face of the polarized cell layer. For example, SV40 infection can occur only from the apical surface. Since virus release also often occurs in a polarized manner from epithelial cells, asymmetric receptor distribution can greatly influence the course of infection and the pathway of virus spread in an infected animal (Tucker et al. 1994).

Antibody-mediated enhancement

Although the presence of a cognate receptor is usually a prerequisite for infection, some virus–cell interactions can occur through intermediate molecules for which both the virus and the cell have affinity. Paradoxically, virus-specific antibodies can play this role and actually promote virus uptake because some cells express a receptor for the Fc portion of the antibody molecule (Porterfield 1986; Halstead 1994; Tirado and Yoon 2003). In this way, the immune system can collaborate in the spread of infection by circumventing the requirement for a virus-specific receptor (Mason et al. 1994). The pathogenesis of infections by both dengue virus and HIV can be exacerbated by antibody-mediated enhancement of infectivity, but the phenomenon is probably irrelevant for viruses such as polio, in which interaction with the cognate receptor mediates an essential structural change in the virion (Consequences of receptor binding).

Consequences of receptor binding

As mentioned at the start of this section, receptor binding initiates virus entry into the cell and, at least in some cases, destabilizes the structure of the virion so that it begins to disassemble. Before binding to the receptor, poliovirus is stable at pH 2 and can therefore enter the body through the strongly acidic environment of the stomach. However, reaction with PVR causes a major conformational change in the capsid that involves swelling, loss of a small internal protein (VP4), and extrusion of the hydrophobic N terminus of VP1 in preparation for its interaction with membranes (Flore et al. 1990; Racaniello 1992; Gomez Yafal et al. 1993). However, only a few of the poliovirus particles that interact with the receptor are internalized. Substantial numbers of these antigenically altered particles, which can no longer bind the receptor and have therefore lost their infectivity, dissociate from cells during poliovirus infection and may play a role in decoying the immune response. In the case of some rhinoviruses, reaction with the receptor is sufficient to release the viral RNA and produce empty capsids, whereas in other cases this requires exposure to mildly acidic conditions such as those encountered during passage through the endocytic pathway into the cytoplasm (Giranda et al. 1992; Greve and Rossmann 1994) (see Penetration and uncoating). These observations suggest that receptor binding and acid pH may co-operate to initiate picornavirus disassembly. In the case of HIV, binding to the receptor CD4 causes the release of the viral attachment protein gp120 from the particle, exposing a hydrophobic fusion peptide whose interaction with membranes

mediates the next step in viral entry (see Penetration and uncoating).

When the natural function of the receptor is transmembrane signaling, virus binding can trigger a physiological response even without internalization. It is thought that Epstein–Barr virus can activate B lymphocytes by binding to the C3d complement receptor (Hutt-Fletcher 1987). Moreover, this type of effect can be widely disseminated because infected cells often secrete soluble forms of the viral attachment protein. Some of the complex effects of HIV on T-lymphocyte function may be mediated directly by the phosphorylation of CD4 and the consequent transmembrane signaling that is caused by the binding of gp120.

Entry accessory factors

There are many instances in which the ability of a virus to bind to the surface of a cell is sufficient for uptake, but there are others where something else is needed. For example, rodent cells that express human CD4 fail to become infected with HIV unless they also express the human membrane protein fusin, which is required for penetration of the virus–receptor complex into the cell (Feng et al. 1996). In the case of adenovirus, initial receptor binding by the fiber protein must be followed by an interaction between the penton base protein of the virus and cellular integrins in order for internalization to occur (Wickham et al. 1993). The distinction between secondary receptors and entry accessory factors, and the roles that each plays in virus uptake are unclear and will probably remain so until more details of this multistep process are known.

Release from receptors

For viral progeny to spread most effectively, some mechanism is needed to ensure release from receptors expressed by the primary infected cells. In general, a combination of virus-mediated receptor down-regulation and the inhibition of protein synthesis contribute to this requirement, but some viruses that bind to sialic acid also carry specific 'receptor-destroying enzymes' that remove terminal sialic acid residues from oligosaccharides. Along with the HA protein described in the section entitled Viral attachment proteins and sites, particles of influenza A virus and influenza B virus have a second surface glycoprotein (NA) that has neuraminidase (sialidase) activity. Although the presence of this enzyme may allow infecting virions to 'browse' the cell surface during entry, its only essential roles in infection are to prevent infected cells from trapping progeny virus particles and to eliminate the self-aggregation that would otherwise result from HA binding to its own oligosaccharides (Liu et al. 1995). Particles of influenza C virus and some coronaviruses, whose attachment proteins bind to *N*-acetyl-9-*O*-acetylneuraminic acid, carry an esterase that likewise mediates destruction of receptors. In the latter case, and in some paramyxoviruses, the receptor-binding and receptor-destroying activities are both present in the same molecule (HE and HN, respectively), raising interesting questions about their interrelationship and regulation.

PENETRATION AND UNCOATING

Virus particles assemble in cells as very stable structures that are often able to withstand harsh extracellular environments, but when re-exposed to intracellular conditions they spontaneously disassemble. In some cases, binding to the receptor contributes to this dramatic change in virion stability (Consequences of receptor binding), but an important role is played by the paths that viruses follow as they enter cells. Depending on the type of virus, its genome must cross one, two, or three lipid bilayers between binding to the receptor at the plasma membrane and reaching its intracellular destination. During infection, all viral genomes must penetrate the plasma membrane; those of enveloped viruses must also cross the viral membrane, and those that replicate in the nucleus also need to traverse the nuclear membrane. Virion proteins play active roles in these transmembrane passages, and have been sculpted by natural selection to transfer the viral genome to the appropriate cellular compartment. Some stages of virion disassembly and genome uncoating invariably accompany membrane penetration (Hoekstra and Kok 1989; Marsh and Helenius 1989; Carrasco 1994; Greber et al. 1994; Lanzrein et al. 1994; Poranen et al. 2002).

Two pathways of virus entry

Although some viral receptors naturally transport small molecules (see Table 3) (Dautry-Varsat and Lodish 1984), it seems that not even the smallest virus is directly carried across the plasma membrane by its receptor. Instead, enveloped viruses transfer their nucleocapsids across membranes by fusing with them, a reaction that achieves simultaneous envelope removal and cell entry. Fusion is mediated by specific virion surface proteins that can fuse lipid bilayers (Viral fusion proteins), and some nonenveloped viruses probably achieve the same result by inserting capsid proteins into a cellular membrane (Uncoating of nonenveloped viruses). For many viruses, both with and without envelopes, activation of the ability to fuse with membranes requires exposure to a mildly acidic environment (pH 5–6); such viruses enter cells by receptor-mediated endocytosis (see Figures 2 and 7) into endosomes whose contents then become acidified by an ATP-driven proton pump. The result is fusion of the virus with the membrane of the endosome and release of the viral

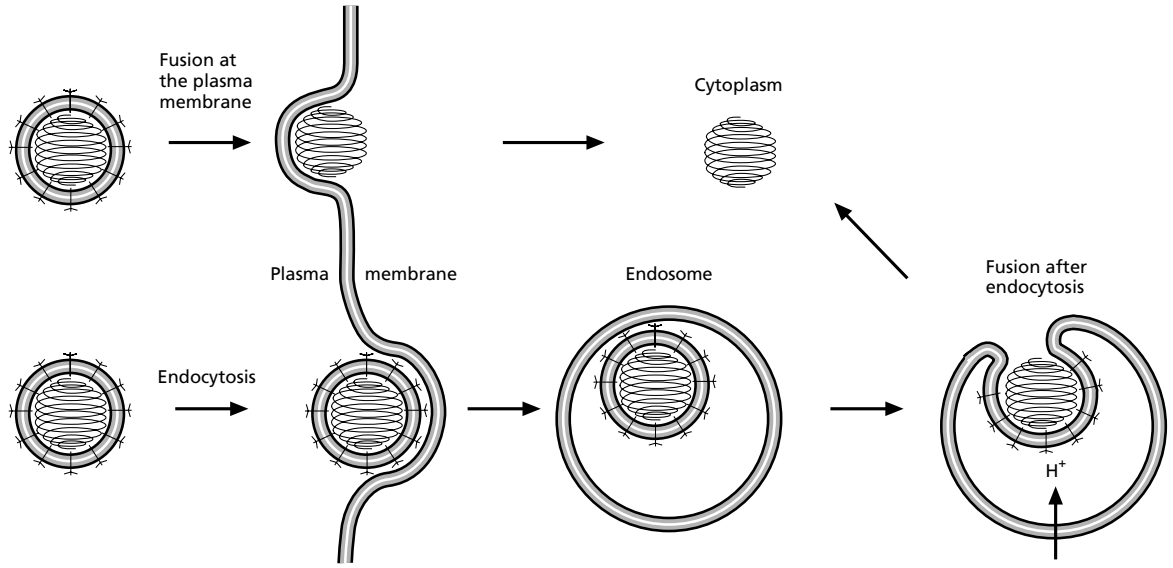

Figure 7 *Two pathways of enveloped virus entry: fusion at the plasma membrane or fusion after endocytosis.*

genome into the cytoplasm. Other viruses can fuse without being exposed to low pH, and can therefore enter the cytoplasm directly by fusion with the plasma membrane (Figure 7).

Infection by viruses that enter through endosomes can be inhibited by lysosomotropic agents such as ammonium chloride or chloroquine which raise the endosomal pH, whereas viruses that enter at the plasma membrane are insensitive to these reagents. The pathway of entry that leads to a productive infection is thus determined largely by the properties of the viral protein responsible for membrane fusion: whether exposure to low pH is required to activate it. In general, viruses in the herpes-, polyoma-, paramyxo-, retro-, and rotavirus families can enter cells by fusion with the plasma membrane in a pH-independent manner, whereas those in the adeno-, alpha-, bunya-, flavi-, orthomyxo-, picorna-, reo-, and rhabdovirus families need to pass through an acidic endosome. However, there are several individual exceptions to these family rules.

The ability of many viruses to fuse with cellular membranes is responsible for a common cytopathic effect of viral infection: the formation of multinucleated syncytia by cell-to-cell fusion. This is due to the abundant expression of the viral proteins that cause membrane fusion (see Viral fusion proteins) on the surface of infected cells, where they can interact with both infected and uninfected neighbors ('fusion from within'). Cell fusion creates a pathway for the local spread of an infection by which a virus can partly elude the immune system. For respiratory syncytial virus, a member of the paramyxovirus family, the extensive syncytium formation that accompanies infection both in the respiratory tract and in cell culture was used in naming the virus and in diagnosing infections. Another paramyxovirus, Sendai virus, has been widely used by cell biologists as a laboratory reagent to induce the formation of heterokaryons by 'fusion from without.'

Viral fusion proteins

Some viruses (e.g. the paramyxoviruses) have separate envelope glycoproteins for receptor binding and membrane fusion; others (e.g. influenza and the retroviruses) combine the two functions into a single viral protein. Despite their variety of structures, however, the fusion proteins of enveloped viruses have features in common. They all contain two hydrophobic regions: a transmembrane domain by which they are anchored in the viral envelope, and a fusion peptide of 16–26 nonpolar amino acids in the ectodomain of the protein that interacts with the target membrane (Schlesinger and Schlesinger 1987; White 1990, 1992; Doms et al. 1993; Smith and Helenius 2004; Earp et al. 2005). Formation of a bridge between the viral and cellular membranes by means of divalent anchoring is thought to mediate membrane apposition (Figure 8), an essential step in fusion (Bentz 1993).

The hydrophobic nature of the fusion peptide must remain masked, both during translation, to allow it to pass through the membrane of the endoplasmic reticulum (ER), and during virus assembly and release, to prevent premature activation of its fusogenic potential. For these reasons, fusion peptide sequences are initially buried, both in the primary sequences and in the oligomeric structure of fusion proteins. A maturational cleavage event, which sometimes occurs after virus release, places the fusion peptide sequence at a newly created N terminus, as in the influenza HA structure where it forms the N terminus of HA2 (see Figure 3) or in the HIV gp120/gp41 structure in which it is the N terminus

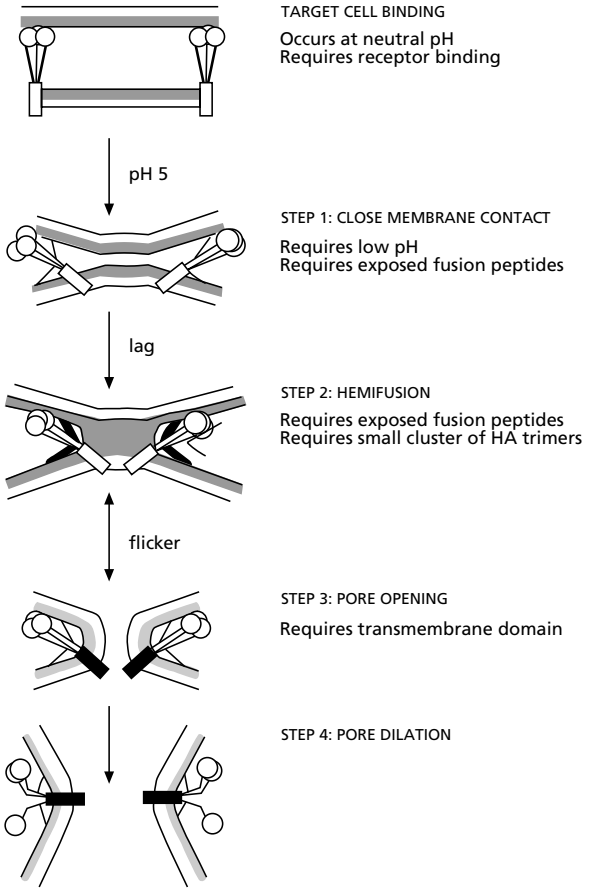

Figure 8 *Steps in HA-mediated membrane fusion (from White (1994)).*

of gp41. However, the two cleavage products remain associated with one another, sometimes by disulfide bonds, in an oligomeric structure that continues to mask the fusion peptide. In the case of influenza HA, rearrangement of the subunits of the trimer is necessary to expose their fusion peptides to the target membrane, and it is likely that a major conformational change of this sort is a common feature of the activation of fusion proteins (see Mechanisms of membrane fusion).

Different viruses prevent premature activation of their fusion proteins in different ways. For Sendai virus, the required cleavage of the fusion protein precursor is mediated by a protease at the membrane of the target cell. For HIV, receptor binding dissociates gp120 and thereby exposes the hydrophobic N terminus of gp41. For Semliki Forest virus, the fusion protein monomer is maintained as an inactive heterodimer with the viral attachment protein until receptor binding and exposure to low pH release it to form the homotrimer that is fusogenic (Kielian 1995). For some paramyxoviruses, fusion requires both the attachment protein HN and the fusion protein F, because binding of HN to its receptor somehow activates the fusion protein, its partner in the viral envelope (Lamb 1993). For influenza A virus, where exposure to low pH triggers the conformational change that activates HA, the protein is chaperoned during its synthesis and maturation by the viral M2 protein, which acts as a transmembrane proton channel to regulate the pH in the cellular compartments through which the maturing HA must pass (Pinto et al. 1992). Another role for the influenza virus M2 protein as an ion channel is described under Transit to the nucleus.

Mechanisms of membrane fusion

The three-dimensional structure of the neutral form of HA (see Figure 3) raised some perplexing questions about how it mediated membrane fusion. Because the receptor-binding site is 135 Å from the transmembrane domain and about 100 Å from the fusion peptide, it was not clear how, after receptor binding, the protein could closely juxtapose the viral envelope in which it was anchored with the target membrane for insertion of the fusion peptide. Some of these problems were solved when it was discovered that a region of HA2 underwent a massive conformational change at the pH of membrane fusion, resulting in a 100 Å relocation of the

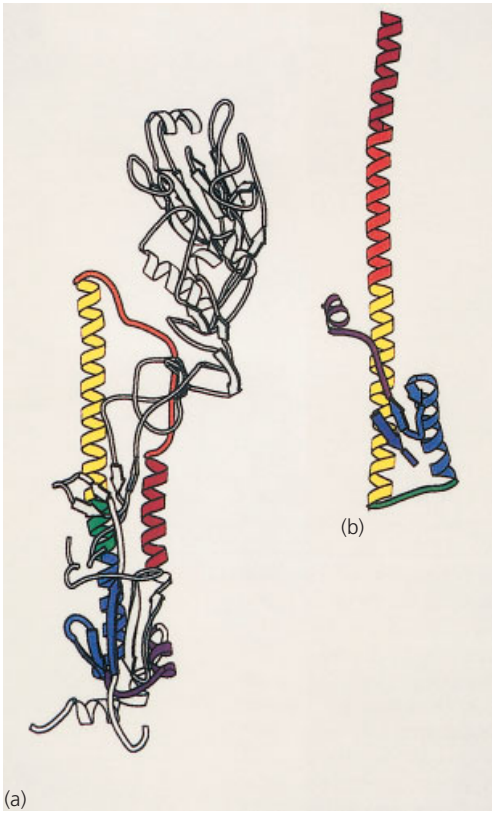

Figure 9 *The conformational change induced by low pH in* influenza virus *HA.* **(a)** *The neutral pH form of the HA1,2 monomer is shown in the same orientation as in the HA trimer shown in Figure 3.* **(b)** *The low pH form of the HA2 monomer. Corresponding regions are colored identically (from Bullough et al. (1994)).*

fusion peptide to one apex of the molecule (Figure 9) (Carr and Kim 1993; Bullough et al. 1994).

In this new location, membrane insertion of the N terminus of HA2 is easy to envisage, although it is not clear whether this and other fusion peptides are inserted into their target membranes vertically, obliquely, or horizontally, as random coils or perhaps as amphipathic α-helices. Unfortunately, the new HA2 structure does not reveal the relative positions of the fusion peptide and the anchor domain, so the way that these regions and the receptor-binding site collaborate to mediate membrane fusion is still unclear (Carr and Kim 1994; Stegman 1994; Hughson 1995; Skehel and Wiley 2000). When last seen in the low pH structure, the C terminus of HA2 was heading in the direction of the fusion peptide (Figure 9), raising the possibility that the acid-induced conformational change brings the anchor and fusion peptides (and hence perhaps the viral and cellular membranes) into close proximity with one another. However, there is much yet to be discovered about the mechanism of membrane fusion and several models have been proposed that involve hemifused intermediates (Figure 8), inverted micelles, proteinaceous pores, or intermembrane stalks (Stegman 1994). It is interesting that an engineered mutant of HA that is anchored only in the outer membrane leaflet rather than traversing the lipid bilayer mediates only hemifusion, showing that the anchor domain plays different roles in mixing the lipids of the two leaflets (Kemble et al. 1994).

Uncoating of nonenveloped viruses

Nonenveloped viruses are also destabilized during cell entry, by interactions with their receptors (see Consequences of receptor binding), and in some cases by exposure to endosomal pH, reducing conditions or low intracellular calcium ion concentrations. Although entry of nonenveloped viruses into the cytosol cannot be achieved by membrane fusion, it is possible that the hydrophobic N terminus of VP1 of some picornaviruses may play the role of a fusion peptide. It is buried in the capsid structure but becomes exposed when the virus binds to its receptor, and may perhaps be inserted into the cell membrane as a pentamer derived from one of the 12 fivefold axes of the icosahedral virion. The internal protein VP4, which exits the virus particle after receptor binding, is myristylated at its N terminus, and could thereby also interact with membranes. Such a complex might form a hydrophilic transmembrane channel through which the viral RNA could pass into the cytosol (Figure 10) (Mosser et al. 1994; Johnson 1996). Despite the external protein symmetry of icosahedral virions and nucleocapsids, it is possible that the asymmetry of the nucleic acid inside confers different properties on some of the capsomers and that these differences are exploited during virion disassembly. Whether the RNA enters the cytosol in a polar manner as depicted in Figure 10 remains to be determined. However, the capsid proteins of infecting alphavirus particles are transferred to 28S ribosomal RNA (Singh and Helenius 1992), thus releasing the viral RNA genome for translation. The disassembly of tobacco mosaic virus and cowpea chlorotic mottle virus in plants also occurs cotranslationally, by ribosomes displacing capsid proteins from the viral RNA during the initial round of protein synthesis (Verduin 1992), and a similar possibility exists for extraction of the RNA from positive-strand RNA animal viruses.

For adeno- and reoviruses, whose genomes do not interact directly with ribosomes, partially disassembled subviral particles exit the endosome by lysis or permeabilization of the vesicle membrane. As in the examples described above, it is the acidic environment, sometimes in conjunction with proteolytic cleavage of viral structural proteins, that activates the virus parti-

cles to disrupt the endosomal membrane (Dryden et al. 1993).

Transit to the nucleus

Viral genomes that replicate in the nucleus need to travel there from where they entered the cytosol. For a herpesvirus particle infecting a neuron, this may be a journey of several centimeters during which the viral nucleocapsid is transported by axonal flow (Herpesviruses: general properties). In less extreme cases, transport mechanisms that are thought to involve interactions with the cytoskeleton deliver the viral genome or nucleocapsid to the cytoplasmic face of pores in the nuclear membrane. For adeno- and herpesviruses, whose nucleocapsids are too large to enter the nucleus intact, a final stage of uncoating occurs at the nuclear pores to release the viral DNA into the nucleus. In contrast, most retroviruses require the natural breakdown of the nuclear membrane that occurs during mitosis, and they are therefore restricted to infection of dividing cells.

Influenza virus replicates in the nucleus but assembles its progeny in the cytoplasm and therefore faces unusual problems of compartmentation. The binding of viral nucleocapsids to the matrix protein (M1), which is responsible for their transport out of the nucleus in preparation for virus assembly, must be disrupted at the start of infection in order to permit the incoming viral genome to migrate into the nucleus. This is another function of the viral M2 protein; it creates acid-activated ion channels in the viral envelope which open at the low pH of the endosome to admit ions into the interior of the virion, thereby releasing the viral nucleocapsids from their association with the matrix protein (Hay 1992; Helenius 1992; Marsh 1992). The anti-influenza drug amantadine inhibits this process by blocking the ion channel activity of the M2 protein.

Poxvirus uncoating requires viral gene expression

In the uncoating mechanisms described above, components of the infecting virions played active and essential roles, but the expression of new viral genes was not necessary. Members of the poxvirus family, however, uncoat by a two-stage process in which the second stage depends on viral gene expression (Poxvirus replication). Vaccinia virus, for example, is taken up by receptor-mediated endocytosis (Hugin and Hauser 1994; Chang et al. 1995). On release of the nucleocapsid core into the cytosol, a viral DNA-dependent RNA polymerase that is part of the core begins to transcribe several viral genes, among them one for a protease that triggers the second stage of uncoating that releases the

viral DNA into the cytosol in preparation for genome replication.

EFFECTS ON HOST-CELL METABOLISM

An incoming virus particle faces a formidable challenge in subverting the metabolism of the host cell to its own ends. Depending on the virus, a single copy of its genetic program dominates one that is 10^4–10^6 times larger and already being expressed. To meet this challenge, viruses have evolved a wide variety of ways to manipulate the intracellular environment so that it can better support their replication. These include changes in intermediary metabolism, particularly of deoxyribonucleotides, as well as effects on the synthesis, processing, transport, and turnover of cellular macromolecules. Viruses achieve dominance by combining mechanisms that enhance the expression of viral genes with those that interfere with the host. Many of the latter perturbations have detrimental effects on the infected cell that result in viral pathogenesis and disease (Pathogenesis of viral infections), but it seems that few if any of them evolved with the primary purpose of causing cellular damage. On the contrary, viruses, like all successful parasites, survive not because they kill the host but because they avoid inducing its premature demise.

The nature of the initial biosynthetic reaction – DNA, RNA, or protein synthesis – and where it occurs in the infected cell depend on the genome strategy of the virus (Table 4). Most DNA genomes replicate in the nucleus, whereas most RNA genomes replicate in the cytoplasm, although the pox- and orthomyxoviruses are notable exceptions to this generalization. The retro- and hepadnaviruses are difficult to classify in this regard because their genomes alternate between RNA and DNA during each replication cycle. Whatever the initial biosynthetic reaction, a mechanism that most viruses use to help them attain dominance over the cell is to differentiate their infectious cycles into an early phase, when the viral genomes are present in low copy-number and direct the synthesis of catalytic amounts of viral replication proteins, and a late, postreplicative phase, when the abundant progeny genomes direct the synthesis of stoichiometric amounts of structural proteins.

DNA metabolism

Host-cell DNA replication occurs only during the S phase of the cell cycle, in a tightly regulated manner that is co-ordinated with the cell cycle as a whole. It requires pools of deoxyribonucleotides, replication enzymes, continuous protein synthesis, and access to appropriate anchor points on the nuclear matrix (Challberg and Kelly 1989; Echols 1990; Challberg 1991; Stillman et al. 1992). Viruses perturb this process to different degrees, depending on how much they rely on it for their own replication. Retroviruses, for example, which integrate DNA copies of their genomes into host chromosomes, ensure their replication by the expression of oncogenes that drive the cell relentlessly through the cell cycle, but do not otherwise affect cellular DNA replication (Prions of humans and animals). At the other end of the spectrum, the elaborate genomes of herpes- and poxviruses replicate with almost complete autonomy, to the extent that infection by HSV blocks cells from progressing to S phase, and infection by vaccinia virus even causes cellular DNA degradation (Kelly et al. 1988).

DEOXYRIBONUCLEOTIDE BIOSYNTHESIS

Most cells in the body continue to make RNA and protein throughout their lives, but many terminally differentiated cells stop dividing and therefore suppress DNA synthesis. For a virus with a DNA genome to be able to replicate in such cells, it must not only circumvent this suppression or provide the necessary enzymes for DNA replication (or both) but also restore the cellular pools of deoxyribonucleoside triphosphates (dNTPs). Even in dividing cells, the metabolic load imposed by viral DNA synthesis can exceed the capacity of the cell and require continuous replenishment of the dNTP pools. This problem is particularly acute for the poxviruses, which replicate their DNA in the cytoplasm (Poxvirus replication).

Two distinct mechanisms have evolved to relieve this constraint: DNA viruses with relatively small genomes, such as the polyoma- and adenoviruses, induce cells to enter S phase, when the cellular genes for the necessary enzymes are naturally expressed. This is the basis for the oncogenic potential of viruses in these families (Jansen-Durr 1996), which is described in Viral oncogenicity. In contrast, larger DNA viruses in the herpes- and poxvirus families have genomes with sufficient capacity to encode viral versions of some of the critical enzymes of nucleotide metabolism. Figure 11 shows the major pathways of dNTP biosynthesis in animal cells, with the enzymes encoded by either herpes- or poxviruses (or both) underlined. It is presumed that the genes for these enzymes were acquired from the host during viral evolution and serve to liberate these viruses from dependence on S phase. However, the genes are usually dispensable for virus replication in cultured cells, which are metabolically active and cycling.

Although these virus-specified enzymes catalyze the same reactions as their cellular counterparts, their substrate specificities and regulatory properties are often somewhat different, which makes them feasible targets for the development of antiviral agents (The emergence and re-emergence of viral diseases). For example, the antiherpetic drugs acyclovir and ganciclovir are analogues of guanosine that can be phosphorylated by the thymidine kinase enzyme of HSV, but not by that

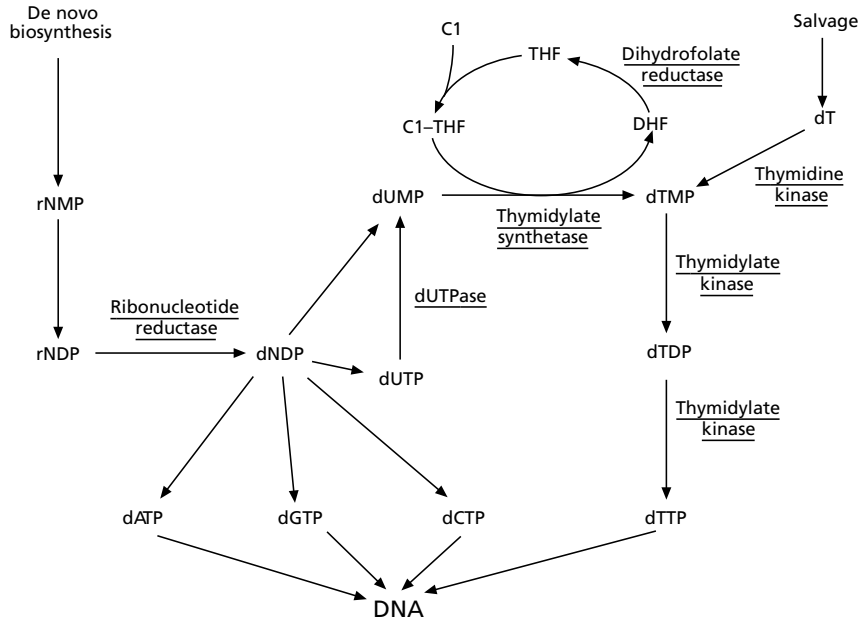

Figure 11 *Pathways of deoxyribonucleotide biosynthesis. Underlined enzymes are encoded by some herpes- or poxviruses.*

of the host. Because the 5′-triphosphates of these drugs act as chain terminators during DNA synthesis, they block DNA replication specifically in HSV-infected cells. However, the propensity of viral genomes for mutation and the facile selection of drug-resistant mutants create problems for the long-term use of antiviral agents that are similar to those encountered with antibiotics. For example, suppression of vaccinia virus replication by hydroxyurea, which inhibits ribonucleotide reductase by a radical scavenging mechanism, readily selects for resistant mutants that contain multiple copies of the gene for one of the subunits of the viral enzyme (Slabaugh et al. 1989). Nevertheless, the virus-specific enzymes of nucleotide metabolism that are encoded by the larger DNA viruses provide versatile genetic tools, as well as possible targets for the development and testing of antiviral agents. The possibility is also being explored of incorporating the HSV thymidine kinase gene into suicide vectors targeted to tumor cells to render them sensitive to acyclovir (Morgan and Anderson 1993).

DNA REPLICATION

As described above, DNA viruses with small genomes stimulate the host cell to provide them with many of the enzymes they need for DNA replication. Polyomaviruses, such as SV40, induce S phase in infected cells by the action of a single viral gene product, large T antigen, which is expressed early in the infectious cycle (Fanning and Knippers 1992). This viral protein binds to the cellular tumor-suppressor protein pRb (Wiman 1993), displacing transcription factors of the E2F family to which it is normally bound (Nevins 1992). These transcription factors switch on several cellular genes involved in cell cycle control and DNA replication, including the genes for DNA polymerase α, the enzyme that replicates the viral genome. T antigen also binds to another tumor-suppressor protein, p53, and relieves the cell cycle block that is normally imposed by this protein (Ludlow 1993; Ludlow and Skuse 1995). Thus, by expressing a single viral protein, SV40 prepares the cell for DNA replication and gains access to the enzymes necessary to catalyze it. During a productive infection, viral DNA replication will ensue, but the properties of large T antigen are those of an oncogene, and expressed on its own it will transform cells and cause tumors (whence it derives the name of Tumor antigen). In the related papillomaviruses, the inactivation of pRb and p53 is delegated to two viral proteins, E7 and E6, respectively (Vousden 1993; Farthing and Vousden 1994).

With DNA genomes three to six times larger than those of the polyomaviruses, adenoviruses (
Adenoviruses) have sufficient genetic capacity to encode three of the proteins necessary for DNA replication: DNA polymerase, a genome-linked terminal protein involved in the initiation of viral DNA synthesis, and a single-stranded DNA binding protein. However, they still need to push the cell into S phase to establish supportive conditions. This push is mediated by two early viral gene products, E1A and E1B, which together perform the functions described above for SV40 T antigen: binding to the tumor-suppressor proteins pRb and p53, respectively (Moran 1993).

In addition to the enzymes of nucleotide metabolism (Figure 11), HSV encodes seven proteins that are directly involved in DNA replication (

Alphaherpesviruses). By providing so much of the replication apparatus itself, HSV gains independence from the cell cycle and attains a degree of autonomy that lets it replicate in highly differentiated cells, such as neurons. Similarly, encoding most or all of their replication machinery enables poxviruses to replicate their DNA in the cytoplasm (Poxvirus replication).

Two families of animal viruses synthesize DNA by a pathway that has no cellular counterpart, that of reverse transcription of RNA. Retro- and hepadnaviruses both encode an RNA-dependent DNA polymerase (reverse transcriptase) that catalyzes this unique reaction which is central to their mechanisms of genome replication (Prions of humans and animals; and 56, Hepatitis delta virus). The enzyme is a structural component of virus particles from both families and it catalyzes the initial biosynthetic reactions of their infectious cycles, the synthesis of viral DNA. Retroviruses also encode an integrase enzyme that recombines the proviral DNA into the genome of the host.

Because cellular DNA replication depends on continuous protein synthesis, it is inhibited by many DNA and RNA viruses as a consequence of their effects on translation (see Protein metabolism). The viruses probably benefit from the increased availability of nucleotides. Inhibition also results from the ability of viral DNA molecules to displace cellular DNA from anchor points on the nuclear matrix that are thought to provide the necessary structural framework for DNA replication. It has been suggested that competition for these sites may modulate the interaction between viral and host cell DNA replication (Cook 1991), and, in accordance with this idea, components of the cell's replication machinery are also redistributed within the nucleus following HSV infection (de Bruyn Kops and Knipe 1988).

DNA MAINTENANCE AND TRANSFER

Viral DNAs can be stably maintained in the host cell either by integration into a cellular chromosome, as with the retroviruses, or in the form of extrachromosomal circular episomes, as with papilloma and hepadnavirus DNAs and during latent infections with herpesviruses. In the integrated state, retroviral DNAs use both the origins and the enzymes of the cell for replication, but episomal DNAs contain their own *cis*-acting replication origins and usually express *trans*-acting viral proteins to assist in their replication and maintenance. In general, the long-term co-existence of viral and host DNAs in the same cellular compartment creates possibilities for the transfer of genetic information in both directions. Transfers from virus to cell are exemplified by the many instances of cellular transformation mediated by the incorporation of oncogenes from DNA tumor viruses (Teich 1991). Transfers from cell to virus are considered to have been responsible for the acquisition of proto-oncogenes during evolution of the RNA tumor viruses and for the integration of a cellular retrotransposon into baculovirus DNA (Friesen and Nissen 1990).

DNA MODIFICATION AND DEGRADATION

Unlike bacteria, eukaryotic cells do not generally contain DNA restriction/modification enzyme systems to protect themselves against invading DNA, although a few examples have been found of such enzymes being induced or encoded by viruses of eukaryotes. A family of DNA viruses that infect the green alga *Chlorella* encode DNA methyltransferases and sequence-specific endonucleases that resemble restriction enzymes of prokaryotes (van Etten et al., 1988, 1991; van Etten and Meints 1999). Cells infected by frog virus 3, an iridovirus, express a cytosine methyltransferase that protects the viral DNA against degradation by a virus-encoded DNase (Murti et al. 1985). Poxviruses, on the other hand, rely on subcellular compartmentation to achieve specific degradation of host DNA. Vaccinia virus particles contain a DNase that enters the host-cell nucleus early in infection and degrades the cellular DNA. The liberated nucleotides are recycled into viral DNA to such an extent that the incorporation of exogenous thymidine via the thymidine kinase pathway is almost completely suppressed during the later stages of viral DNA synthesis. Degradation of cellular DNA also occurs as a result of the induction of apoptosis in response to infection by some viruses (see Apoptosis). During this process, internucleosomal cleavage of chromatin produces a characteristic ladder of DNA fragments that can be resolved by agarose gel electrophoresis. Finally, the genomes of vaccinia virus and HSV encode uracil DNA glycosylases that are thought to be involved in viral DNA base excision repair (Dodson et al. 1994; Millns et al. 1994).

RNA metabolism

Whatever the initial biosynthetic event in infection, sooner or later every virus has to deliver mRNA to the cytoplasm to direct viral protein synthesis. Because the nature of the problem varies with the genetic strategy of the virus, virus families have evolved different mechanisms to ensure efficient transcription of viral genes and to disrupt the expression of host-cell genes (Nevins 1989; Tevethia and Spector 1989).

PREFERENTIAL SYNTHESIS OF VIRAL RNAS

Three general mechanisms have been identified that promote transcription of viral genes at the start of infection:

1. seduction of the cellular RNA polymerase (pol II) by means of a strong promoter/enhancer sequence in the viral DNA (e.g. polyoma- and adenoviruses);
2. import of a new transcription factor that redirects pol II to the viral DNA (e.g. HSV);

3 import of a new RNA polymerase with specificity for the viral genome (e.g. poxviruses and all negative-strand and double-stranded RNA viruses).

These three distinct mechanisms are described below.

Enhancers

Studies of the early SV40 promoter, which directs pol II to transcribe the viral T antigen gene, were the first to discover the *cis*-acting DNA element now known as an enhancer which increases the level of transcription from a minimal promoter on a DNA molecule (Tjian and Maniatis 1994). Enhancers work by recruiting cellular transcription factors which are often differentially expressed in different cell types, so the properties of the viral enhancer can determine which types of cell are able to support replication of the virus (Drapkin et al. 1993). For example, human papillomavirus (Papillomaviruses) is restricted to replication in keratinocytes partly because the enhancer for its E6 and E7 oncogenes must be recognized by a keratinocyte-specific transcription factor.

Transcription factors

In HSV infection, the viral DNA enters the nucleus together with a virion structural protein called α-*trans*-inducing factor (α-TIF) (or VP16) which is necessary for efficient transcription of the α class of viral genes that are expressed immediately after infection. α-TIF works in conjunction with the cellular transcription factor Oct-1 to recruit pol II to the Oct-1-binding sites (ATGCAAAT) that are present in the promoters for the α-genes (Kristie and Sharp 1993). Among the products of α-gene expression are at least two other transcription factors that change the specificity of the cellular polymerase to prepare it for the next stage of viral gene expression, transcription of the β-genes (Herpesviruses: general properties; and Alphaherpesviruses). In general, DNA viruses switch transcription from one temporal class of genes to the next by the synthesis of viral factors that act directly or indirectly on the corresponding RNA polymerases. Some of the properties of the SV40 T antigen and the E1A/E1B proteins of adenovirus that provide examples of this were described in the section entitled DNA metabolism. Transcription factors for immediate–early genes (e.g. HSV α-TIF) are synthesized late in the preceding infectious cycle because they themselves are encoded in late viral genes. It is not yet known what prevents them from becoming active until the start of the next infection.

RNA polymerases

Many virus families have genomes that cannot be transcribed by any cellular polymerase and must therefore be presented to the cell in conjunction with a functional virus-specific transcriptase. For example, although poxvirus genomes are composed of double-stranded DNA, infection delivers them to the cytoplasm, which lacks RNA polymerase activity, and anyway their promoter sequences are unrecognizable by the nuclear RNA polymerases (Poxvirus replication). To ensure transcription of their genes under these conditions, infecting poxvirus particles contain a multisubunit transcription complex that is activated once the viral core reaches the cytoplasm. It is guided specifically to the early viral genes by a viral early transcription factor (VETF) that is bound to early promoters, in conjunction with a polymerase-associated protein (RAP94) that is responsible for recruiting the subunits of the transcription complex during virus assembly in the previous infection (Zhang et al. 1994).

RNA viruses whose genomes consist of either double-stranded RNA or single-stranded negative- or ambisense RNA face the same problem and solve it in the same manner: infection delivers the genome complexed with a virus-encoded RNA-dependent RNA polymerase that transcribes the viral genes (Ishihama and Barbier 1994; O'Reilly and Kao 1998). In many cases, virion-associated enzymes then cap, methylate and polyadenylate the primary transcripts to produce functional mRNAs. The following virus families use this strategy: reo-, orthomyxo-, paramyxo-, rhabdo-, filo-, bunya-, and arenaviruses (see Table 4).

PERTURBATIONS OF CELLULAR RNA METABOLISM

Every step of cellular RNA metabolism is disrupted by one virus family or another: transcription, processing, transport from the nucleus to the cytoplasm, translation, and RNA degradation. These effects usually give the viral genes a competitive advantage, although in some cases the advantage may be too slight to be demonstrable during a single infectious cycle. Effects on translation are described in Protein metabolism, the others below.

RNA synthesis

The expression of oncogenes by tumor viruses results in a stimulation of cellular RNA synthesis as a consequence of cell cycling. In contrast, most nononcogenic viruses inhibit cellular transcription, although the mechanisms may be consequences of the inhibition of protein synthesis or the rearrangement of cellular chromatin, or both. The benefit to the virus is presumed to be decreased competition for ribonucleoside triphosphates, and in some cases the increased availability of pol II. Curiously, VSV, a rhabdovirus that replicates entirely in the cytoplasm (Rhabdoviruses), also inhibits cellular transcription. The 46 nucleotide (nt) VSV leader RNA migrates into the nucleus early in

infection, associates with the cellular La protein and can inhibit pol II. However, the idea that leader RNA is responsible for the inhibition of transcription in infected cells has been challenged, and the physiological significance of these effects is unclear.

Influenza virus disrupts cellular RNA synthesis in an unusual manner that is directly related to its own mechanism of transcription (Orthomyxoviruses: influenza). By endonucleolytic cleavage, the viral RNA polymerase removes 10–13 nt fragments that include the cap from the 5′ ends of newly made cellular transcripts, and uses these fragments to prime the synthesis of viral mRNAs in the nucleus of infected cells (Lamb and Krug, 2001). The effect is to transfer the caps from cellular mRNA precursors to viral messages, thereby labilizing the former and ensuring the translatability of the latter. Bunyaviruses (*Bunyaviridae*) use a similar cap-snatching mechanism to derive the 5′ ends of their mRNAs, except in this case the cap donors are mature cellular messages that are already in the cytoplasm (Kolakofsky and Hacker 1991).

RNA processing and transport

For viruses that replicate in the nucleus, RNA splicing is usually an important control point in gene expression. In the interests of genetic economy, DNA viruses with small genomes frequently splice their primary transcripts in several different ways, both to derive multiple mRNAs from a single promoter and to access two overlapping reading frames in the same region of the viral genome. Retroviruses use alternative splicing patterns too, but they also need a mechanism to allow the export to the cytoplasm of unspliced RNA to encode some of the viral structural proteins and to be encapsidated into progeny virions. Complex retroviruses, such as HIV, achieve this by the interaction between a viral protein rev, itself the translation product of a spliced message, and a specific RNA sequence in the viral genome (the rev-response element (RRE)). This interaction allows the export of viral RNAs that still contain complete introns and would otherwise be retained in the nucleus (Gait and Karn 1993; Cullen 1994). In simpler retroviruses such as Mason–Pfizer monkey virus, the function of the rev/RRE complex is performed instead by a small *cis*-acting constitutive RNA transport element (CTE) that somehow promotes the export of unspliced viral RNAs to the cytoplasm (Bray et al. 1994; Ernst et al. 1997).

The NS1 protein of influenza virus inhibits splicing of both viral and cellular mRNA precursors by binding to their poly(A) tails and blocking spliceosome function, but in this case the unspliced host cell transcripts are retained in the nucleus, where they provide a source of the capped oligonucleotides that are needed as primers for viral transcription. Phosphorylation of NS1 regulates this inhibition to permit the release of viral mRNAs to the cytoplasm (Lamb and Krug 2001). Yet another variation is provided by adenovirus, the system in which splicing was originally discovered (Berget et al. 1977; Chow et al. 1977). Splicing is not inhibited in infected cells, and indeed primary adenovirus transcripts are extensively and differentially spliced to access many different open reading frames from a few promoter sites (Adenoviruses). However, two of the early proteins (E1B and E4) specifically inhibit the export of processed cellular mRNAs from the nucleus and promote that of late viral mRNAs, resulting in the preferential synthesis of viral proteins. It is likely that further studies of the ways that different viruses impinge on the processing and transport of cellular transcripts will deepen our understanding both of virus–cell interactions and of the regulation of mRNA synthesis in uninfected cells (Krug 1993).

RNA degradation

The pathways and control of mRNA degradation in eukaryotic cells are not fully understood (Katze and Agy 1990; Rajagopalan and Malter 1997) but, as with RNA processing and transport, viral genetics provide powerful experimental tools to assist research in this area. Both HSV and vaccinia virus infections increase the rate of host mRNA degradation and thereby inhibit cellular protein synthesis (Rice and Roberts 1983; Strom and Frenkel 1987). The effects are not specific for cellular messages, because viral mRNAs are turned over equally fast, but the greater vigor of viral transcription is better able to compensate for the short mRNA half-lives, which also facilitate the rapid transitions from expression of one temporal class of viral genes to the next. For HSV-1, the ability to induce mRNA labilization has been mapped to the *vhs* gene (for viral host shut-off), which encodes a virus structural protein. The vhs protein in the virion is sufficient to trigger mRNA degradation in some cells, although it is not known whether it works directly as a nuclease or by activating a host cell degradative mechanism. In vaccinia virus, the gene responsible for enhanced mRNA turnover has not been mapped, but mutations that subtly affect the function of the viral RNA polymerase can cause massive nonspecific RNA degradation by producing abundant double-stranded RNA which activates the cellular 2–5A RNase L system for RNA breakdown (Bayliss and Condit 1993) (see Induction and actions of interferons, and

The role of cytokines in viral infections).

Protein metabolism

The synthesis, processing, and transport of viral proteins lie at the heart of the overlap between viral and cellular metabolism, because, whereas most viruses encode specific enzymes or factors that participate in viral transcription and genome replication, they all depend on

the host cell for the entire machinery of protein synthesis and transport. One consequence of this is that translation, which is such an effective target for antibacterial agents, is not available as a target for the development of antiviral drugs.

PROTEIN SYNTHESIS

The rate of protein synthesis from a particular mRNA is influenced by many factors (Lodish 1976). In eukaryotic cells, most translational control is exerted at initiation (Merrick 1990; Gale et al. 2000), and a schematic picture of this multistep reaction is shown in Figure 12. Because of its complexity, the regulation of this process is not yet fully understood, but the following factors all play a part: the abundance of the mRNA, its 5′ cap structure, the local nucleotide sequence context and secondary structure surrounding its initiation codon, whether it is translated on free or membrane-bound polysomes, and the availability and activity of cellular initiation factors (Hershey 1990, 1993; Kozak 1991a; Wek 1994). Two prominent control points among the latter are eIF4F, the cap-binding complex, and eIF2, which binds the initiator met-tRNA to the 40S ribosomal subunit. Both of these initiation factors are altered in some virus-infected cells, as described below (Kozak 1986; Schneider and Shenk 1987).

Initiation in uninfected eukaryotic cells usually involves recognition by eIF4F of the 7-methylguanylate cap at the 5′ end of cellular mRNA, followed by association of the mRNA with a complex that contains the 40S ribosomal subunit, met-tRNA$_i$ and eIF2 (Figure 12). eIF4F is a cap-dependent RNA helicase that is required for the translation of almost all capped messages. On a very small number of cellular mRNAs and on picornaviral RNAs, initiation occurs at an internal ribosome entry site (IRES), in a manner that is independent of the 5′ cap and eIF4F. In both cases, the 40S subunit then scans in a 3′ direction until it encounters the first AUG codon. If the local sequence context of this AUG is favorable for initiation, the 60S ribosomal subunit joins the complex, eIF2 dissociates and the synthesis of the polypeptide chain begins. Initiation efficiency is influenced most by the identity of the nucleotides in the −3 and +4 positions relative to the AUG, the sequence . . . C**R**CCAUG**G** . . . being optimal for initiation, but

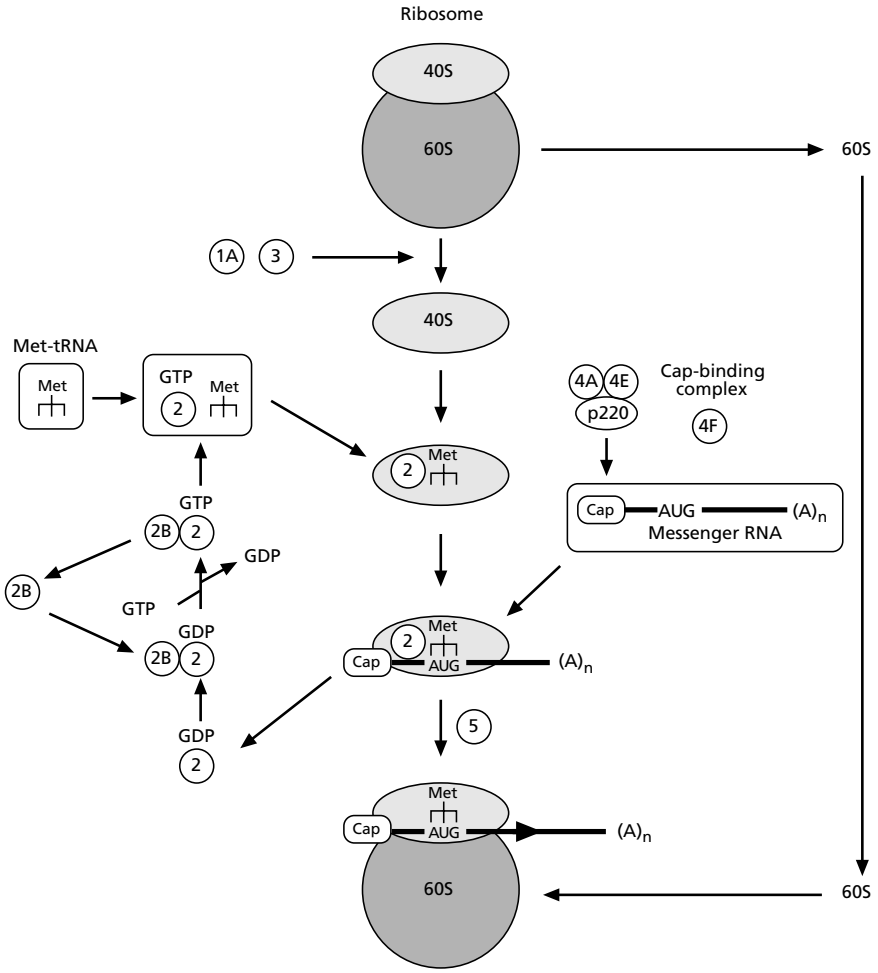

Figure 12 *Mechanism of initiation of protein synthesis in animal cells. The numbered circles represent the initiation factors.*

other features of the mRNA 5′ end including its secondary structure can also exert effects (Kozak 1989, 1991a, b, 1992a, b, 1994). Although eukaryotic protein synthesis usually starts at the first AUG codon, if its context is unfavorable for initiation the 40S subunit can continue scanning until it finds the next and starts there instead. In rare instances, alternative initiation codons, including non-AUG codons, are used to derive more than one translation product from a single mRNA, as in the case of the P mRNA of some paramyxoviruses (Curran et al. 1986) (see General properties of paramyxoviruses). When eIF2 dissociates from the initiation complex it is bound to GDP, but before it can form another met-tRNA-40S subunit complex for another round of initiation, it must exchange this GDP for GTP, a reaction that requires initiation factor eIF2B (Figure 12). In several metabolic situations including viral infection, this exchange reaction is a major site at which protein synthesis is regulated, as described below (Hershey 1993).

Host shut-off and the preferential translation of viral mRNAs

The inhibition of host-cell protein synthesis is one of the most obvious metabolic consequences of viral infection, and it has been the focus of much research using several different virus systems (see Ehrenfeld (1993) for reviews). Unfortunately, although it is easy to demonstrate the phenomenon, it has proved difficult to elucidate its mechanisms, because, somewhat surprisingly, viruses shut off host protein synthesis in different ways and even closely related viruses can use completely different mechanisms (Table 5). Cytocidal viruses such as polio and vaccinia inhibit host translation profoundly, but retroviruses, which depend on the cell's continued growth and survival, scarcely perturb host protein synthesis at all. Many other viruses lie between these two extremes. Some of the conflicts in the literature on this subject may be because some viruses use more than one mechanism or use different mechanisms when infecting different cell types.

Because viral and host mRNAs compete directly for translation, viruses have evolved mechanisms that favor the synthesis of their own proteins, often at the expense of the cell's. However, the total amount of translation occurring in infected cells is almost always less than that in uninfected cells, because infection generally reduces the overall capacity of the cell for protein synthesis. Rather than simply displacing host mRNAs, viral messages are preferentially translated against the background of a progressive inhibition of total protein synthesis to which they are relatively resistant. For this reason, how viruses inhibit host protein synthesis and the mechanisms they use to achieve preferential translation of their own mRNAs are interdependent.

Several such mechanisms have been identified (Table 5). To begin with, the abundance of individual viral mRNAs is usually greater than that of most cellular mRNAs, because of vigorous viral transcription and the high gene copy-number that results from viral genome replication. In the herpes- and poxviruses, this effect is magnified by an increased rate of mRNA breakdown (see RNA metabolism). In addition, many viral mRNAs have a competitive advantage whose structural basis is not fully understood (Garfinkel and Katze 1993; Kozak 1994). Part of the answer lies in the nucleotide sequence context of their initiation codons, but strong contexts, although common, are not ubiquitous in viral mRNAs (Kozak 1986). Their 5′ untranslated regions are usually shorter than those of host mRNAs, and the resulting proximity of the cap to the initiation codon and other undefined structural features of their 5′ ends may also favor translation.

For polio- and rhinoviruses, the mechanism is clear and elegant (Sonenberg 1987; Jackson et al. 1991; Wycoff 1993; Thompson and Sarnow 2000): infection results in the expression of a viral protease (2A), which mediates cleavage of a component (p220 or the γ subunit) of the cellular cap-binding complex, eIF4F (Etchison et al. 1982; Etchison and Fout 1985). The

Table 5 *Mechanisms of inhibition of host-cell protein synthesis*

Virus	Mechanism	Reference
Herpes simplex	Degradation of host (and viral) mRNAs	Strom and Frenkel (1987)
Vaccinia	Degradation of host (and viral) mRNAs	Rice and Roberts (1983)
Polio	Inactivation of eIF4F-γ by cleavage	Etchison et al. (1982)
Rhino	Inactivation of eIF4F-γ by cleavage	Etchison and Fout (1985)
Adeno	Inactivation of eIF4F-α by underphosphorylation	Huang and Schneider (1991)
	Inactivation of eIF2B-β by phosphorylation	O'Malley et al. (1989)
Vesicular stomatitis	mRNA abundance	Lodish and Porter (1981)
	Not mRNA abundance	Schnitzlein et al. (1983)
	Affinity for ribosomes	Nuss et al. (1975)
	Interference with eIF2 function	Centrella and Lucas-Lenard (1982)
	Interference with eIF3/4B function	Thomas and Wagner (1983)

result is inactivation of the initiation factor and consequent inhibition of translation of capped mRNAs. Viral RNA is immune to this inhibition because it is translated from an IRES and naturally lacks a 5′ cap (Meerovitch and Sonenberg 1993). In virions, polio- and rhinovirus RNAs carry a covalently attached viral protein (VPg) at their 5′ ends, while the translated form of the viral RNA starts with a 5′-monophosphate, pUp (Picornaviruses).

It is surprising that cleavage of the cap-binding protein is unique to polio- and rhinoviruses, and does not occur in cells infected with other picornaviruses, despite the fact that all their RNAs contain IRES elements, are translated in a cap-independent manner, and mostly shut-off host protein synthesis (Duncan 1990). Because it is incontrovertible that picornaviruses are all descended from a common ancestor, their use of different shut-off mechanisms suggests either that an ancestral mechanism was replaced in some but not other descendants or that the ancestor did not inhibit host translation and that the present-day mechanisms evolved separately after divergence. Taken with the fact that polio- and herpesvirus mutants that cannot shut off host translation are only partly debilitated for growth (Bernstein et al. 1985; Strom and Frenkel 1987), this evidence suggests that inhibition of host protein synthesis, though beneficial, is not essential for virus replication. Indeed, a general selection method has been developed for the isolation of nonconditional viral mutants that are deficient in host protein shut-off (Francoeur et al. 1987).

The activity of the cap-binding complex is also reduced in adenovirus-infected cells, but in this case it is by reduced phosphorylation of the α subunit (eIF4A, which is the cap-binding protein itself) rather than by cleavage of p220 (Huang and Schneider 1991; Zhang and Schneider 1993). Because adenovirus mRNAs are capped, the rationale for eIF4F inactivation is less obvious than with the picornaviruses. However, it seems that the tripartite leader, a 200-nt RNA segment that is common to the 5′ end of all late adenovirus mRNAs (Adenoviruses), renders them less dependent for translation on the helicase activity of eIF4F than are cellular messages.

Changes in the level of phosphorylation of another initiation factor, eIF2, are responsible for the regulation of protein synthesis under many different conditions of cellular stress, but in this case it is increased phosphorylation that interferes with initiation. As shown in Figure 12, eIF2 needs to exchange its bound GDP for GTP between each round of initiation, and this exchange requires the formation of a complex with eIF2B. Phosphorylation of the α subunit of eIF2 prevents the dissociation of this complex, and, because eIF2B is scarce relative to eIF2, a modest increase in the level of phosphorylation inhibits initiation profoundly. As described in Induction and actions of interferons, this mechanism is part of the cell's response to viral infection that is enhanced by treatment of cells with interferon. Increases in the phosphorylation of eIF2-α occur in cells infected with adeno- and reoviruses, but it is unclear whether these are part of the virus-mediated inhibition of host mRNA translation or the cell-mediated inhibition of the virus. Nevertheless, this regulatory mechanism is a key point in the balance between viral and cellular protein synthesis, as shown by the fact that vaccinia virus encodes a homologue of eIF2-α, and several other viruses perturb the phosphorylation of eIF2-α in other ways (see Viral mechanisms to evade cellular defenses).

Access to alternative open reading frames

In addition to alternative RNA splicing (see RNA metabolism) and transcriptional editing (Cattaneo 1991; Jacques and Kolakofsky 1991), some viruses use translational frameshifting to express open reading frames that would otherwise be inaccessible in an mRNA. Retroviruses in particular use this mechanism to make proteins that they require only in small amounts, like the gag–pol precursor to the reverse transcriptase in Rous sarcoma virus (Jacks and Varmus 1985). Frameshifting is promoted by specific 'slippery' sequences in the mRNA, which, often in conjunction with adjacent 'hungry' codons and strong RNA secondary structure, persuade ribosomes occasionally to switch reading frames during translation (Brierley 1993). Whether viral infection modulates the intrinsic propensity of the ribosomes for frameshifting is not yet clear. In other retroviruses, synthesis of the gag–pol precursor is achieved by suppression of the termination codon at the end of the *gag* gene (Prions of humans and animals).

PROTEIN PROCESSING

During and after their synthesis, viral proteins are processed along many of the same reaction pathways as cellular proteins, and, because they offer such attractive experimental subjects, they have been widely used as model systems for the study of these pathways. There are also several cases in which protein processing reactions are mediated by viral enzymes or modified by viral proteins, and this is a frequent cause of CPEs.

Folding and oligomerization

Viral proteins must adopt the correct tertiary and quaternary structures before they become functional and, in many cases, before they can be transported to their ultimate destinations in the cell. These reactions have been examined in particular detail for viral envelope glycoproteins such as influenza HA, which must undergo glycosylation, folding and trimerization before it can move from the ER, via the compartments of the Golgi apparatus, to the cell surface in preparation for virus assembly (Gething et al. 1986; Doms et al.

1993; Byland and Marsh 2005). Folding is facilitated by interaction with a cellular protein BiP which resides in the lumen of the ER and binds transiently to newly made glycoproteins. BiP belongs to the hsp70 family of cellular proteins that are induced by heat shock and other types of stress, and it functions both to catalyze protein unfolding/refolding and to target misfolded and mutant proteins for degradation (Pelham 1988; Hartl 1996; Paulsson and Wang 2003).

Proteolytic cleavage

Many viral proteins are cleaved during maturation, by either cellular or viral proteases. For example, the activation of viral fusion proteins by cleavage (see Viral fusion proteins) is often catalyzed by members of the furin family of cellular proteases (Klenk and Garten 1994a,b). However, viral proteolysis is used most extensively by the nonsegmented, positive-strand RNA viruses of the picorna-, toga-, and flavivirus families (Picornaviruses; Togaviruses; and Flaviviruses). These viruses synthesize large polyprotein precursors that undergo multiple co- and post-translational cleavages catalyzed by several viral proteases to yield the mature viral proteins (Krausslich and Wimmer 1988; Strauss 1990; Dougherty and Semler 1993; Ryan and Flint 1997; Ryan et al. 1998; ten Dam et al. 1999). They are forced into this strategy of gene expression by a combination of their need to make several different viral proteins from a single mRNA and the reluctance of eukaryotic ribosomes to initiate at more than one site on a message. In contrast, viruses whose transcriptional mechanisms allow them to synthesize individual mRNAs and those with segmented genomes rely less heavily on proteolytic processing.

The assembly of icosahedral and more complex viral structures is also often accompanied by cleavage of structural protein precursors, which imposes a rigid order on the assembly process and can result in large-scale conformational changes in the maturing virion, often coincident with the acquisition of stability and infectivity (Guo 1994). Both in picorna- and in nodaviruses, the final maturational cleavage event occurs inside the assembled virion, and is catalyzed by the interior of the capsid itself. It is interesting that the assembly of helical nucleocapsids generally seems not to involve protein cleavage.

Glycosylation

All enveloped viruses carry surface glycoproteins whose glycosylation is mediated by the normal cellular pathways of carbohydrate attachment and processing. Both *N*- and *O*-linked oligosaccharides are found but viral proteins with the former modification are more common.

Whether glycosylation is required for glycoprotein transport and function varies from one case to another, and probably reflects the different roles that oligosaccharides can play in determining the native structures of individual proteins. In certain cases, however, the influence of glycosylation can be dramatic: the presence or absence of a particular *N*-linked oligosaccharide in influenza HA that partially obstructs the HA1–HA2 cleavage site can have a profound effect on viral virulence because it determines which proteases can cleave the HA precursor, and hence how the virus can spread in the infected animal (Deshpande et al. 1987).

Phosphorylation

Viruses and cells interact with one another by phosphorylation in both directions: the phosphorylation of cellular proteins by viral kinases and the phosphorylation of viral proteins by cellular kinases. Prominent among the former are reactions catalyzed by the tyrosine kinases that are encoded by the oncogenes of Rous sarcoma virus (v-src) and its relatives. In these cases, the major targets of kinase action are cellular proteins involved in cell cycle regulation whose activities are perturbed by phosphorylation. Conversely, cellular kinases can phosphorylate viral proteins and thereby modify their activities. For example, phosphorylation of the P protein of VSV by cellular casein kinase II enables it to form oligomers, which is an essential step in viral transcription (Gao and Lenard 1995).

Other covalent modifications

A wide variety of other covalent modifications of viral proteins have been described in different virus–cell systems, including N-terminal acetylation, acylation (with both palmitate and N-terminal myristate), ADP ribosylation, isoprenylation, methylation, and sulfation. In most cases the cellular enzymes that catalyze these reactions are widely distributed and therefore do not restrict virus replication, but the effects of many of the modifications on the properties of viral proteins have yet to be fully explored.

PROTEIN TRANSPORT

Viral proteins are transported to the appropriate intracellular sites for replication and assembly by interaction with cellular protein trafficking pathways: to the plasma membrane via the ER and Golgi apparatus, to the nucleus, and to other organelles. Despite the disruption of the cytoskeleton and the extensive changes in cell morphology that often accompany infection, these trafficking pathways are generally not disrupted. Many viral proteins contain signals that define their destination in the cell, such as the hydrophobic signal sequences of integral membrane glycoproteins which, by binding to the signal recognition particle, commit the proteins to

ER membrane insertion and transport along the exocytic pathway. Nuclear localization signals, which were first identified in the SV40 T antigen (Kalderon et al. 1984), target the corresponding viral proteins to the nucleus for replication and assembly. Proteins that contain *cis*-acting signals such as these are transported to the appropriate cellular compartment even when they are expressed from a vector in the absence of other viral proteins. In contrast, proteins that lack signals of their own can co-localize by binding with targeted proteins. A striking example of the influence of such signals on virus assembly is provided by the observation that a point mutation in a retroviral matrix protein determines whether the viral nucleocapsids assemble in the cytoplasm or at the plasma membrane (Rhee and Hunter 1990).

PROTEIN DEGRADATION

As described above, viruses in many families encode proteases with new specificities that can cleave cellular as well as viral polypeptides. It is likely that the resulting exposure of new N termini (Varshavsky 1992) to the protein degradation pathways (Hershko and Ciechanover 1992; Rubin and Finley 1995) will enhance the rate of turnover of specific proteins in cells infected with these viruses, although, apart from the cleavage of eIF-4F described above, few specific examples have yet been described.

CELLULAR RESPONSES TO VIRAL INFECTION

Because viruses are a threat to the survival of cells and organisms, it is inevitable that cells and organisms should have evolved defense mechanisms to counteract them. It is similarly inevitable that those viruses with sufficient genetic capacity should have evolved countermeasures to circumvent these defenses. In higher vertebrates, the major defense of organisms against infection is provided by the mucosal, humoral, and cell-mediated arms of the immune system, which are described in The immune response to viral infections. The major defenses at the cellular level are the interferon (IFN) system (see below and The role of cytokines in viral infections), RNA interference (Hannon 2002; Ding et al. 2004), and the mechanisms of stress response and apoptosis. The interplay between the processes of virus replication, these cellular responses and the corresponding viral evasion mechanisms determines the outcome of infection at the cellular level.

Induction and actions of interferons

The IFNs are a family of cytokines that elicit profound physiological changes in the cells with which they interact, including the development of resistance to viral infection. In higher vertebrates, the IFN system acts within a few hours of infection, long before the onset of the immune response, to limit the spread of the infection and thus to diminish its severity. Indeed, many of the familiar early symptoms of a viral infection in humans are attributable to IFN action. IFNs are synthesized and secreted by most cell types in response to infection and some other stimuli, and they exert their effects by inducing the expression of several IFN-responsive genes. Understanding the system as a whole, therefore, requires knowledge of the IFN genes, how they are induced, the IFN proteins themselves, and how they interact with their target cells, how these interactions trigger expression of the IFN-inducible genes, and, finally, how the products of these latter genes render the cell resistant to viral infection and mediate their other effects. Although much remains to be learned about this complex and multifunctional regulatory system, intense research in recent years has clarified many important aspects. Here is presented only an overview of the IFN system; for more details the reader should consult The role of cytokines in viral infections or a review article (Revel and Chebath 1986; Pestka et al. 1987; Samuel 1988, 1991; Staeheli 1990; Sen and Lengyel 1992; Sen and Ransohoff 1993; Johnson et al. 1994; Sen 2001; Malmgaard 2004).

INTERFERONS

Four distinct types of IFNs have been identified and characterized: α, β, γ, and ω. Although their properties overlap to the extent that they are all recognized as IFNs, they are secreted by different cell types in response to different inducers and they exert somewhat different physiological effects on different target cells. In the context of virus–host cell interactions, α, β, and γ IFNs are the most relevant because α and β induce a virus-resistant state in most cell types, whereas IFN-γ primarily modulates aspects of the cell-mediated immune response via its effects on macrophages. Alpha IFNs, which are encoded in a multigene family, are homologous to IFN-β and interact as monomers with the same receptor on the surface of target cells. In contrast, IFN-γ has little homology with the other types and binds as a dimer to two copies of a different cell surface receptor (Walter et al. 1995).

INTERFERON INDUCTION

Alpha and β IFNs are induced and secreted from many different cell types in response to infection by most viruses, as well as some other assaults, and these cytokines act as an early warning system that alerts other cells in the body that infection is imminent. In contrast, IFN-γ is produced only by T lymphocytes and natural killer cells, in response to induction by cognate antigens and other T-cell activators. Induction of IFNs occurs by transcriptional activation of the IFN genes, and,

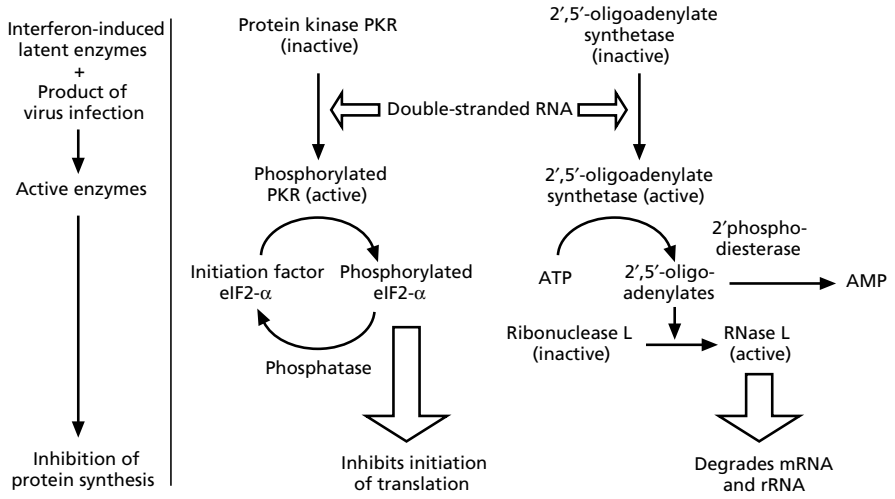

Figure 13 *Mechanisms of the antiviral action of interferons.*

although many of the mechanistic details remain obscure, a satisfying picture is emerging for the induction of IFN-β. It has long been known that IFN-β can be induced by treating cells with double-stranded RNA, and indeed the production of double-stranded RNA may be a general mechanism by which viruses induce IFNs. Among the cellular targets for double-stranded RNA is a cytoplasmic protein kinase called PKR, which is also involved in the mechanism of IFN action (see below). On activation by binding to double-stranded RNA, PKR phosphorylates I-κB, the inhibitory subunit of the transcription factor NF-κB (Karin and Hunter 1995). Phosphorylation of I-κB allows NF-κB to enter the nucleus where it recognizes specific DNA binding sites and thereby activates the transcription of several genes, including that for IFN-β (Proud 1995).

INTERFERON ACTION

The binding of IFNs to their corresponding receptors initiates signals that are transmitted to the nucleus of the IFN-treated cell via the JAK/STAT pathway. Signal transduction occurs by the activation of a family of tyrosine kinases (Janus kinases (JAK)) that are associated with the cytoplasmic domains of the transmembrane IFN receptors and activated when the receptors are occupied by binding to IFNs. The activated JAKs phosphorylate a family of transcription factors (signal transducing activators of transcription (STAT)), which then migrate from the cytoplasm to the nucleus. Here they form active complexes that bind to interferon-specific response elements (ISRE) present in the promoter sites upstream of IFN-inducible genes, thereby activating their transcription (Williams 1991; Pellegrini and Schindler 1993). Many other polypeptide ligands that exert a wide variety of physiological effects on cells also transmit their signals to the nucleus via the JAK/STAT pathway. The specificity of the ligand/response relationship seems to be maintained by subtle quantitative, qualitative, and temporal differences in the spectra of JAK activation and STAT phosphorylation that are elicited by the different ligands, although much more work is needed to define fully how the integrity of different signals is maintained (Schindler and Darnell 1995; Aaronson and Horvarth 2002).

Although the IFN system was first discovered by the observation that IFN-treated cells are resistant to viral infection, it has since become clear that this is only one aspect of their altered physiology. IFNs can also have profound antiproliferative and immunomodulatory effects, so the physiology of the IFN response in whole animals is complex. The multiple effects of IFNs are mediated by the IFN-inducible proteins of which scores have been identified, but the roles that many of them play in the altered physiology of the IFN-treated cell are still unknown. Best understood are two inducible enzymes that are responsible, in part, for the resistance of cells to infection by several different viruses. These are the protein kinase (PKR) that is also implicated in the induction of IFN-β (see above), and a family of enzymes called 2′,5′-oligoadenylate (2–5A) synthetases (Figure 13).

PKR, a double-stranded RNA-dependent protein kinase

The protein kinase now known as PKR is a 68-kDa polypeptide that is induced by IFN treatment of most types of cultured vertebrate cells (Williams 1999). The enzyme is active only when bound to double-stranded RNA, whereupon it phosphorylates and activates itself, and also phosphorylates the translational initiation factor eIF2-α. This interferes with the initiation of protein synthesis (as described under Protein metabolism and Figure 12), which limits viral replication (Hershey 1990, 1993). Untreated cells contain only basal

levels of PKR and the enzyme is largely inactive because of the absence of double-stranded RNA. IFN-treated cells contain substantial levels of PKR, but it remains inactive until viral infection produces double-stranded RNA, either as an intermediate of RNA replication or as a byproduct of overlapping transcription. In this way, the effects of IFN are fully manifested only after viral infection, a mechanism that restricts the major physiological consequences to the cells where they will have the greatest effect. Viruses have evolved numerous ways to counteract the effects of IFN in general and PKR in particular (see Viral mechanisms to evade cellular defenses), implying not only that the IFN response significantly restricts virus replication in nature, but also that PKR is a central component in the mechanism of resistance to many viruses.

2–5A synthetases

The 2–5A synthetases that are also induced by IFN treatment catalyze the template-independent oligomerization of ATP to form a series of 2′–5′-linked oligomers that are referred to collectively as 2–5A (Ball 1982; Player and Torrence 1998; Rebouillat and Hovanessian 1999). Like PKR, the 2–5A synthetases depend on double-stranded RNA for enzyme activity, so full development of this aspect of the IFN response also requires viral infection of IFN-treated cells. The 2–5A oligomers have the general structure $ppp(A^{2'}p^{5'})_nA_{OH}$, and in cells the trimer and tetramer predominate. In general, 2′,5′-phosphodiester bonds are a biochemical rarity, although single such bonds are formed during RNA splicing (Sharp 1994) and also during the priming of cDNA synthesis by bacterial reverse transcriptase (Shimamoto et al. 1995). The only known function of 2–5A oligomers is to activate an endoribonuclease, RNase L, which is present as a constitutive but latent enzyme in most cell types (Bisbal 1997). On activation by 2–5A, RNase L degrades mRNAs and ribosomal RNAs, and thereby inhibits protein synthesis. The degradation of 2–5A itself by a 2′-phosphodiesterase restores RNase L to its latent state. Thus, in IFN-treated virus-infected cells, PKR and 2–5A synthetase collaborate to restrict virus replication by inhibiting both the initiation and the elongation of polypeptides.

Specificity of IFN action

Although IFN treatment generally induces resistance to a wide range of viruses, the induced gene products play quantitatively different roles in combating infection by different viruses. For example, the 2–5A system seems to be particularly important in the resistance to picornavirus infection, but much less so in the resistance to several other virus families. The murine *Mx* gene is a more extreme example of an IFN-induced resistance mechanism that is effective only against a specific virus family because the Mx protein product makes mice and murine cells resistant to infection by influenza virus, but not by other viruses (Staeheli 1990; Samuel 1991; Haller and Kochs 2002). However, a broader and more complex question is whether IFN action can discriminate generally between viral and cellular events and, if so, how this is achieved. IFN treatment clearly enables organisms and cell cultures to survive viral challenges that would otherwise be lethal, and yet the properties of PKR and 2–5A synthetase provide only a partial explanation for this apparent selectivity. The recognition by these enzymes of double-stranded RNA as a signature of viral infection establishes a mechanism for discriminating between infected and uninfected cells rather than between viral and cellular mRNAs, and in some cases the infected cells are sacrificed to prevent viral replication. In other cases, enzyme activation imposes an indiscriminate but transient suppression of protein synthesis, a situation from which the cell can recover but the virus cannot. Finally, in some situations, the IFN-induced enzymes seem to be preferentially activated in cytoplasmic microenvironments surrounding the viral double-stranded RNA molecules that are responsible for their activation, thus achieving selectivity on the basis of compartmentalization.

It seems likely that combinations of these effects enable PKR and 2–5A synthetase/RNase L, which have no demonstrable specificity for viral mRNAs, nevertheless to discriminate between cellular and viral processes.

VIRAL FACILITATION BY INHIBITION OF THE IFN SYSTEM

Viruses differ in their sensitivity to IFNs, in part because some of them have evolved effective countermeasures against one or more component of the IFN system (see Viral mechanisms to evade cellular defenses). Accordingly, a virus such as vaccinia, which is relatively insensitive, can in some circumstances facilitate the replication of a coinfecting IFN-sensitive virus such as VSV by inhibiting the action of IFN. This contrasts with the more common situation in which coinfecting viruses interfere with one another by a variety of mechanisms that are unrelated to the IFN system (Whitaker-Dowling and Youngner 1987).

Induction and actions of cellular stress proteins

Although viral infection suppresses the synthesis of most cellular proteins by the mechanisms described in the section entitled Protein metabolism, some host cell genes are induced by infection and their proteins are relatively resistant to shut-off. These include the genes that encode the IFNs (see Induction and actions of interferons) and also those for a set of proteins that are generally induced by conditions of metabolic stress,

including heat shock (Jindal and Malkovsky 1994; Sarkar and Sen 2004). Some of the cellular stress proteins normally function as molecular chaperones, and certain viruses exploit these properties to assist their own replication and assembly. This is true of some bacteriophages and has also been suggested for several eukaryotic viruses. For example, the cytoplasmic hsp70 protein binds transiently to the poliovirus capsid precursor, perhaps facilitating its folding and assembly. Similarly, BiP protein, which resides in the lumen of the rough endoplasmic reticulum, binds briefly to newly synthesized integral membrane proteins, such as viral glycoproteins, and assists their maturation (Hartl 1996). In addition to these roles, however, the display of virus-induced stress proteins or their peptide fragments on the surface of infected cells may stimulate immune recognition and participate in the activation of the immune response.

Apoptosis

Metazoan organisms have evolved a highly conserved and tightly regulated cellular pathway called 'apoptosis' which, once triggered, leads irreversibly to cell death (Martin et al. 1994; Martin and Green 1995; Steller 1995; Roulston et al. 1999). Apoptosis is the mechanism by which unwanted cells are eliminated during development, but it is also triggered in response to infection by a wide variety of cytocidal viruses (Vaux et al. 1994; Razvi and Welsh 1995; Everett and McFadden 1999). It is characterized by cell rounding, condensation of chromatin, fragmentation of cellular DNA, blebbing of the plasma membrane, and finally break up of the cell contents into membrane-bound apoptotic bodies that are suitable for ingestion by phagocytes. In the context of viral infection, apoptosis serves as an effective defense mechanism for the organism whereby a relatively small number of cells die altruistically to limit virus spread (Williams 1994). This is reminiscent of the self-sacrifice of some IFN-treated infected cells that was described in the section entitled Induction and actions of interferons. The mechanisms by which viruses induce apoptosis have yet to be fully defined, but changes in membrane permeabilities leading to Ca^{2+} influx, the expression of viral proteases with new specificities, and perturbation of the functions of the cellular tumor-suppressor proteins p53 and pRb may all be involved in different situations.

The most persuasive evidence that the effects of apoptosis in virus–host cell interactions are, on balance, detrimental to the virus comes from the observation that several viruses have evolved countermeasures that delay or prevent the onset of apoptosis (Ink et al. 1995; Razvi and Welsh 1995; Gillet and Brun 1996). For example, cowpox virus expresses an inhibitor of an enzyme that is involved in the apoptotic pathway, the interleukin-1β-converting enzyme (ICE) (Kumar 1995), and it thereby blocks both apoptosis and inflammation (Ray et al. 1992). In the absence of an effective apoptotic response, a normally cytocidal virus, such as Sindbis virus, can instead establish a persistent infection (Griffin et al. 1994; Griffin and Hardwick 1997). Conversely, suppression of apoptosis by the adenovirus E1B oncogene is necessary to allow the induction of cell proliferation that is mediated by the E1A oncogene to result in the transformation of adenovirus-infected cells (White 1993).

VIRAL MECHANISMS TO EVADE CELLULAR DEFENSES

During co-evolution with their hosts, different viruses have adopted several different methods of counteracting the various defense mechanisms, an observation that provides compelling evidence for the efficacy of the corresponding host defenses themselves (Smith 1993, 1994; Levy and Garcia-Sastre 2001). As might be expected, inactivation or deletion of the viral genes involved in these evasion mechanisms generally reduces the virulence of the virus. This aspect of the study of virus–host interactions is particularly informative because it provides a window on the relationships as they exist in nature. Moreover, some of the evasion mechanisms have involved the viral acquisition and adaptation of host genes that benefit the virus in much the same way as the acquisition of an oncogene benefits a retrovirus by ensuring cell cycling and concomitant viral replication. These host-derived genes and their products can provide insight into the heart of the virus–host relationship, as well as potential reagents for the experimental and therapeutic manipulation of the host's defense mechanisms (McFadden 1995).

Evasion of immune responses

Many RNA viruses continually evade the immune responses of the host by mutation. The inability of RNA polymerases to correct their mistakes leads to heterogeneous virus populations or quasi species from which antibody-escape mutants are readily selected (Smith and Inglis 1987; Duarte et al. 1994). For viruses that have segmented genomes (e.g. influenza), this effect is reinforced by the potential for reassortment of RNA segments between viruses with different pedigrees (see Orthomyxoviruses: influenza). With HIV, the continuous generation of antigenic variants within each infected individual eventually overwhelms the ability of the immune system to respond and contributes to the onset of AIDS (see Prions of animals and humans). In contrast, viruses with double-stranded DNA genomes are usually replicated with much greater fidelity and have therefore resorted to other methods of immune evasion. For example, herpesviruses are hidden from immune surveillance during latent infections (Masucci and Ernberg 1994; Wagner 1994; Lewin 1995), and during lytic growth they specifically inhibit the intracellular transport mechanism by which viral peptide

fragments are presented to the cell-mediated immune system (York et al. 1994; Fruh et al. 1995). Adeno-, cytomegalo-, and poxviruses also interfere with peptide presentation, by down-regulating the expression of the major histocompatibility complex class I protein (Smith 1993, 1994). In addition, poxviruses encode a variety of soluble cytokine 'receptors' which are secreted from infected cells to intercept immunostimulatory cytokines (Pickup 1994; Spriggs 1994; Lalani and McFadden 1999) (see also The role of cytokines in viral infections).

Evasion of complement

The complement system is a major host defense mechanism which, on activation, attacks and permeabilizes the surface membranes of enveloped viruses and infected cells. Complement is activated by two tightly regulated pathways: the classical pathway, which requires an antibody response to the infecting virus, and the alternative pathway, which is antibody-independent. Several members of the pox- and herpesvirus families express cell surface or secreted proteins that interfere either with the complement activation pathways or with the formation of the membrane attack complex itself, which attests to the potential efficacy of complement against these viruses (Isaacs et al. 1992; Smith 1994).

Evasion of interferon

In contrast to the ease with which antibody-resistant mutants can be isolated, IFN-resistant mutants seldom arise even when they are deliberately selected for (Novella et al. 1996), probably because IFNs induce several distinct and overlapping antiviral mechanisms. Nevertheless, viruses vary considerably in their intrinsic sensitivities to IFNs, not only because they differentially activate the IFN-induced enzymes but also because some of them deploy specific IFN evasion mechanisms (McNair and Kerr 1992). For example, among the soluble cytokine receptors secreted from poxvirus-infected cells are proteins that decoy both α and γ IFNs (Smith 1993; Pickup 1994; Spriggs 1994; Alcami and Smith 1996). Intracellularly, reovirus and vaccinia virus express double-stranded RNA-binding proteins that interfere with the activation of PKR, whereas adenovirus and Epstein–Barr virus (EBV) synthesize abundant small RNAs (called virus-associated (VA) RNAs and EBV-encoded early RNAs (EBERs), respectively) that compete with double-stranded RNA for PKR binding, but which fail to activate the kinase (Mathews and Shenk 1991; Mathews 1993). Yet other mechanisms are used by poliovirus, which degrades the activated PKR, and by influenza virus, which activates a latent cellular inhibitor of PKR (Katze 1993, 1995). Its role in uninfected cells has yet to be determined. Finally, vaccinia virus expresses a homologue of eIF2-α, which decoys the kinase and protects the authentic initiation factor against phosphorylation. The variety of mechanisms that have evolved to circumvent the PKR system argues strongly that it can potentially restrict the replication of a wide range of viruses. Viral mechanisms to evade the 2–5A system also exist, but they remain to be fully characterized.

SUMMARY

Their large population sizes and high mutation rates allow viruses to evolve much faster than the host organisms on which they depend for replication. For this reason, they will continue to threaten the health of the rest of the biosphere and to shape the evolution of their hosts. However, as described in this chapter, examination of the intricacies of virus–host interactions provides unique insights into these competitive relationships and illuminates almost every aspect of the biology of the host organisms. The future promises an even richer harvest of experimental and conceptual advances in this area, both enhancing our ability to control and prevent viral diseases and increasing our understanding of the mechanistic and evolutionary relationships between viruses and their hosts.

Pathogenesis of viral infections

NEAL NATHANSON AND KENNETH L. TYLER

Introduction	1	Host determinants of susceptibility and resistance	27
Sequential steps in viral infection	1	Acknowledgments	30
Virulence of viruses	15	References	30
Persistent infections	23		

INTRODUCTION

Viral pathogenesis deals with the interaction between a virus and its host. Included within the scope of pathogenesis are the stepwise progression of infection from virus entry through dissemination to shedding, the defensive responses of the host, and the mechanisms of virus clearance or persistence. Pathogenesis also encompasses the disease processes that result from infection, variations in viral pathogenicity, and the genetic basis of host resistance to infection or disease. A subject this broad cannot be treated in a single chapter, and this presentation focuses on the dissemination of viruses and their pathogenicity, while other aspects of pathogenesis will be dealt with in. Several detailed reviews of viral pathogenesis have recently been published (Tyler and Nathanson 2001; Nathanson et al. 2002).

SEQUENTIAL STEPS IN VIRAL INFECTION

One of the cardinal differences between viral infection of a simple cell culture and infection of an animal host is the structural complexity of the multicellular organism. The virus must overcome a number of barriers to accomplish the stepwise infection of the host, beginning with entry, followed by dissemination, localization in a few target tissues, shedding, and transmission to other hosts (Figures 1 and 2).

Entry

SKIN AND MUCOUS MEMBRANES

Some viruses (such as papillomaviruses, poxviruses, and herpes simplex viruses) will replicate in cells of the skin or mucous membranes. It is likely that infections with these viruses are initiated at breaks in the epithelium, just as the skin must be scratched to facilitate a take by vaccinia virus. Mucous membranes represent a minimal physical barrier to infection, but are bathed in mucus that contains immunoglobulin and provides protection by virtue of its viscous nature. Following infection of the skin, viruses may spread further by passage of intact virions or virus-infected macrophages and dendritic cells to the regional lymph nodes.

The epidermis consists of several layers of cells including, from the deepest to the most superficial: the basal germinal layer of dividing cells (malpighian stratum), the granular layer of dying cells (stratum granulosum), and the superficial layer of keratin (stratum corneum). Most viruses that replicate in the skin grow in the germinal cells, and some viruses, such as papillomaviruses, have a selective tropism for these cells (Lowy and Howley 2001). Poxviruses and herpes simplex viruses will also replicate in fibroblasts and macrophages in the dermis (Blank et al. 1951; Roberts 1962b). Some adenoviruses, coxsackievirus A24, and enterovirus type 70 are regularly associated with conjunctivitis, and the conjunctiva may represent a primary portal of entry in such instances. Table 1 lists representative viruses that invade via the skin and mucous membranes.

UROGENITAL TRACT

A considerable number of viruses cause sexually transmitted disease, which is usually acquired by exposure to virus-containing secretions. Infection is initiated either

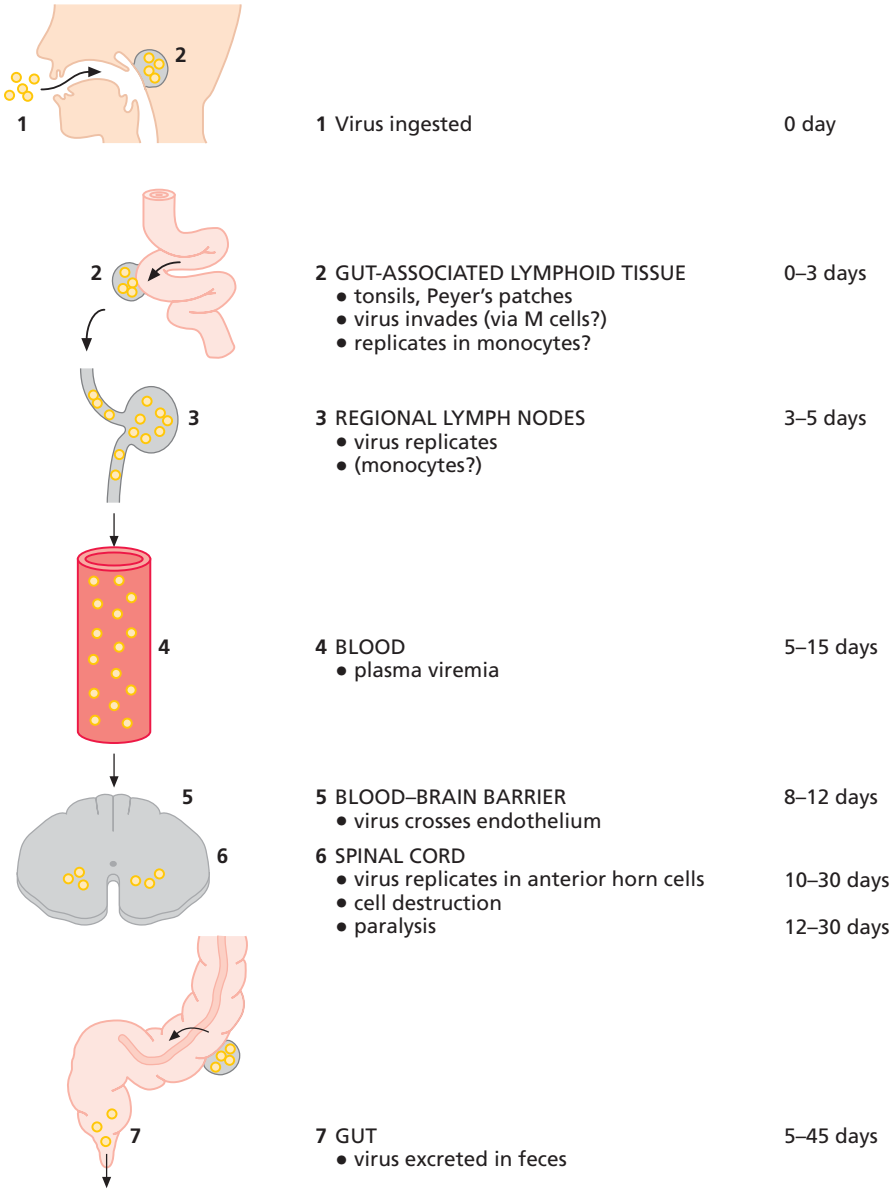

Figure 1 *Spread of* poliovirus*, an example of a virus that can disseminate through the blood (after Nathanson et al. 2002)*

by penetration through breaks in the skin or by direct invasion of the superficial epithelium of the mucous membranes (Pomerantz et al. 1988; Tan et al. 1993).

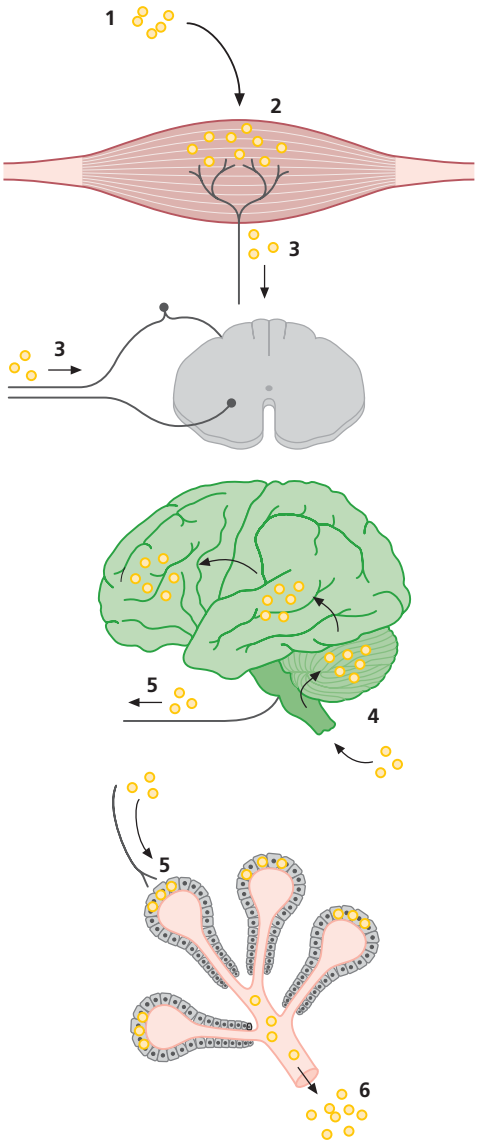
Some sexually transmitted viruses, such as hepatitis B virus (HBV) and human immunodeficiency virus (HIV), are associated with persistent viremia. Thus, contaminated blood, semen, or secretions may introduce HBV directly into the circulation via breaks in skin and membranes. HIV may be trapped on the surface of dendritic cells (Langerhans cells) in the epidermis and then transported to draining lymph nodes where it infects $CD4^+$ T lymphocytes. Also, HIV may infect T lymphocytes in the submucosal tissues, which are the first infected cells detected in experimental vaginal infection of macaques with simian immunodeficiency virus (SIV).

TRANSCUTANEOUS AND INTRAVENOUS INJECTION

Although the skin is a formidable barrier, mechanical injection that breaches the barrier is a natural route of entry for many viruses.

Arboviruses

Many animal viruses are maintained in nature by a cycle that involves a vector and a vertebrate host (Monath 1988), including over 500 individual viruses mainly in the families *Bunyaviridae*, *Flaviviridae*, *Reoviridae*, *Rhabdoviridae*, and *Togaviridae*. When the infected vector takes a blood-meal, virus contained in the salivary gland is injected. Although most viruses that are transmitted by an insect vector replicate in the vector, there are a few instances in



1 VIRUS ENTRY — Day 0
- by bite of rabid animal
- infected saliva is injected

2 STRIATED MUSCLE — Day 1–60
- virus replicates in myocytes

3 PERIPHERAL NERVES — Day 10–60
- virus enters nerve ending
- nucleocapsid carried by fast axoplasmic flow to spinal cord

4 CENTRAL NERVOUS SYSTEM — Day 12–60
- virus travels along neural processes, spreads and replicates
- neuronal dysfunction — Day 50–70
- clinical rabies, death

5 PERIPHERAL NERVES — Day 30–70
- virus travels along peripheral nerves from CNS
- invades salivary gland

6 SALIVARY GLAND — Day 40–70
- virus replicates in acinar cells
- virus is discharged in saliva

Figure 2 *Spread of rabies virus, an example of a virus that spreads through the neural route only (after Nathanson et al. 2002).*

Table 1 *Representative viruses that invade via skin and mucous membranes (modified after Nathanson et al. 2002).*

Site of entry	Route	Virus family	Representative example
Skin	Minor breaks	*Papillomaviridae*	Papillomaviruses
		Herpesviridae	Herpes simplex virus 1
		Poxviridae	Ectromelia virus
Conjunctiva	Contact	*Picornaviridae*	Enterovirus 70
		Adenoviridae	Adenoviruses
Oropharynx	Contact	*Herpesviridae*	Epstein–Barr virus
Genital tract	Contact	*Retroviridae*	HIV
		Papillomaviridae	Papillomaviruses
		Herpesviridae	Herpes simplex virus 2
Rectum	Contact	*Retroviridae*	HIV

which the vector acts only as a flying pin and apparently carries the virus mechanically from one vertebrate host to another. Examples are myxoma virus of rabbits and rabbit papillomatosis virus (Fenner 1983; Dalmat 1958).

Intramuscular injection: rabies

Rabies is the only virus that is maintained in many of its natural cycles by the bite of a sick animal (Baer 1991). Following transcutaneous and intramuscular injection, the virus may either enter the distal processes of peripheral nerves directly or replicate in striated muscle. It can then cross the neuromuscular junction and spread along peripheral nerves to the central nervous system.

Injection or transfusion

Virus may be transmitted accidentally by repeated use of contaminated needles, injection of a virus-contaminated therapeutic, transfusion with virus-contaminated blood or blood products, or tattooing. The agents most frequently involved are those that produce persistent viremias, such as hepatitis B, C, D viruses, cytomegalovirus, and human immunodeficiency virus. Contaminated needles play a major role in transmission, either by parenteral injection of drugs by abusers in developed countries, or by reuse of needles in developing countries. Following parenteral injection, virus appears to be widely disseminated, replicating in those cells for which it has a tropism.

OROPHARYNX AND GASTROINTESTINAL TRACT

The oropharynx and gastrointestinal tract are important portals of entry for many viruses, and enteric viruses may invade the host at a variety of sites from the oral cavity to the colon (Table 2). Some viruses produce localized infections that remain confined to the gastrointestinal tract, whereas others disseminate to produce systemic infection. Most enteric viruses, such as rotaviruses, infect the epithelium of the small or large intestine (Saif 1990; Little and Shadduck 1982) (Figure 3), but some enteroviruses, such as poliovirus, replicate in the lymphoid tissue of the gut and nasopharynx.

There are numerous barriers to infection via the enteric route. First, much of the ingested inoculum will remain trapped in the luminal contents and never reach the wall of the gut. Secondly, the lumen constitutes a hostile environment because of the acidity of the stomach, the alkalinity of the small intestine, the digestive enzymes found in saliva and pancreatic secretions, and the lipolytic action of bile. Thirdly, the mucus that lines the intestinal epithelium presents a physical barrier protecting the intestinal surface. Fourthly, phagocytic scavenger cells and secreted antibodies in the lumen can reduce the titer of infectious virus.

Acid labile viruses, such as rhinoviruses, cannot infect by the intestinal route. Viruses that are successful in using the enteric portal tend to be resistant to acid pH, proteolytic attack, and bile, and some may actually exploit the hostile environment to enhance their infectivity (Clark et al. 1981; Estes et al. 1981). hepatitis A and B viruses illustrate this point – both viruses are excreted in the bile into the intestinal tract, but hepatitis A virus survives and is excreted in an infectious form in the feces while hepatitis B virus is inactivated. As a consequence, only hepatitis A is transmitted as an enterovirus.

Lower gastrointestinal tract

The importance of anal intercourse as a risk factor for hepatitis B and HIV infection has led to the recognition that some viruses can gain entry through the lower gastrointestinal tract. HIV has been detected in bowel epithelium (Levy 1998), but the exact mechanism of HIV infection through the anocolonic portal remains to be determined.

RESPIRATORY TRACT

Respiratory infection may be initiated either by virus contained in aerosols that are inhaled by the recipient

Table 2 *Representative enteric viruses that do and do not cause gastroenteritis (modified after Nathanson et al. 2002).*

Disease	Replicate in the pharynx and/or gastroenteric tract	Virus family	Representative example
Gastroenteritis	Yes	*Astroviridae*	Astroviruses
	Yes	*Caliciviridae*	Norwalk virus
	Yes	*Coronaviridae*	Transmissible gastroenteritis virus of swine

	Yes	*Picornaviridae*	Enteroviruses
	No	*Picornaviridae*	Hepatitis A virus
	Yes	*Adenoviridae*	Adenoviruses

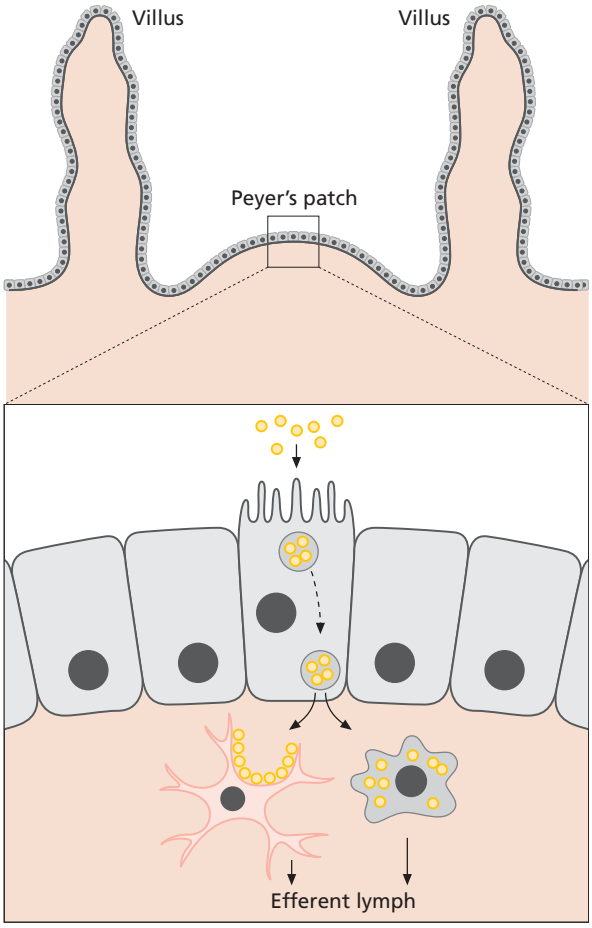

Figure 3 *Virus invasion of the intestine, showing the pathway taken by reovirus in the mouse. The virus binds to M cells, is carried by transcytosis to the basolateral surface, where it infects dendritic cells and macrophages in the lamina propria. This well-studied experimental model probably resembles many natural infections (after Wolf et al. 1981).*

host, or by virus that is contained in nasopharyngeal fluids and is transmitted by hand-to-hand contact. Important groups of viruses transmitted by the respiratory route include rhinoviruses, myxoviruses, adenoviruses, herpesviruses, and poxviruses (Table 3).

Aerosolized droplets are deposited at different levels in the respiratory tract depending upon their size: those over 10 μm diameter are deposited in the nose, those 5–10 μm in the airways, and those <5 μm in the alveoli (Lippmann et al. 1980). Once deposited, the virus must bypass several effective barriers to initiate infection. These barriers include phagocytic cells in the respiratory lumen, a covering layer of mucus, and ciliated epithelial cells that clear the respiratory tree of foreign particles. The temperature of the respiratory tract varies from 33°C in the nasal passages to 37°C (core body temperature) in the alveoli. Viruses (such as rhinoviruses) that can replicate well at 33°C, but not at 37°C, are limited to the upper respiratory tract and, conversely, viruses that replicate well at 37°C, but not at 33°C (such as influenza virus), mainly infect the lower respiratory tract. Most respiratory viruses initiate infection by replicating in epithelial cells lining the alveoli or the respiratory tree, but some viruses will also replicate in phagocytic cells located either in the respiratory lumen or in subepithelial spaces (Douglas et al. 1966; Roberts 1962a).

Spread

Once infection is established at the site of entry, most viruses will spread locally by cell-to-cell transmission of infection. Some viruses remain localized near their site of entry while others spread widely. One determinant of dissemination is the pattern of viral release from polarized epithelial cells. Viruses that are released only at the apical surface of infected cells tend to remain localized, while those that are released at the basal surface tend to disseminate (Tucker and Compans 1992; Jourdan et al. 1997). Usually, the first step in dissemination of the infection is the transport of virus via the efferent lymphatic drainage from the initial site of infection to the regional lymph nodes, either as free virions or in virus-infected phagocytic cells.

VIREMIA

The single most important route of dissemination is the circulation, which can potentially carry viruses to any site in the body. There are several sources of viremia. Virus may enter with the efferent lymphatic flow, or may be shed from infected endothelial cells or circulating mononuclear leukocytes (Charles et al. 1998; Fish et al. 1998). Viruses can circulate either free in the plasma phase of the blood (plasma viremia) or associated with formed elements (cell-associated viremia), and these two types of viremia have quite different characteristics and implications.

Passive viremia is used to describe the entry of a virus inoculum directly into the circulation following injection, without any preceding replication (Figure 4). Passive viremia typically occurs about 3–6 h after injection and disappears within 12–24 h. It has been estimated that about 0.1 percent of the virus in a subcutaneous inoculum enters the bloodstream (Griot et al. 1993b; Pekosz et al. 1995).

Active viremia is used to designate viremia caused by the active replication of virus in the host. In some instances, active viremia may occur in two phases, a primary viremia in which virus spreads from a focal site of entry and a secondary viremia generated after infection has occurred and virus has initially replicated in peripheral tissues, such as endothelium, tissue macrophages, liver, muscle, or other sites (Oaks et al. 1998). An example of an active viremia is shown in Figure 5, in which the virus appears in the plasma a few days after infection and lasts for about 1 week.

Table 3 *Representative viruses that invade via the nasopharynx or respiratory tract, according to localization of disease (modified after Nathanson et al. 2002).*

Localization of disease	Virus family	Representative example
Upper respiratory	*Picornaviridae*	Rhinoviruses
	Adenoviridae	Adenoviruses
Lower respiratory	*Coronaviridae*	Bovine coronaviruses
	Orthomyxoviridae	Influenza viruses
	Paramyxoviridae	Respiratory syncytial virus
	Bunyaviridae	Sin Nombre virus
No respiratory illness	*Togaviridae*	Rubella virus
(± systemic illness)	*Paramyxoviridae*	Mumps virus
	Bunyaviridae	Hantaan virus
	Arenaviridae	Lassa fever virus
	Reoviridae	Reovirus
	Papovaviridae	Murine polyomavirus
	Herpesviridae	Varicella-zoster virus
	Poxviridae	Variola virus

The initial lag period is the interval required for tissue replication and shedding into the circulation. Termination of viremia is often quite abrupt and coincides with the appearance of neutralizing antibody in the serum. When an infected animal is treated with an immunosuppressive regime, the viremia may not be cleared quickly, but persist for longer periods (Nathanson and Cole 1971).

Plasma viremia reflects a dynamic process in which virus continually enters the circulation and is removed. The rate of turnover of virus within the plasma compartment is best expressed as transit time, the average duration of a virion in the blood compartment. Typically, transit times range from 1–60 min and tend to decrease as the size of the virions increases (Mims 1964). Circulating viruses are removed by the phagocytic cells of the reticuloendothelial system, principally in the liver (Kupffer cells), and to a lesser extent in the lung, spleen, and lymph nodes. The fate of viruses that are ingested by Kupffer cells is quite variable and may be an important determinant of pathogenesis. Ingested virions may be degraded, may transit macrophages to underlying parenchyma without replicating, or may replicate in macrophages with or without spread of infection to underlying parenchymal cells. Once the host has developed circulating antibody, plasma virus is very rapidly neutralized in the circulation (Figure 5), and virus–antibody complexes bind to Fc receptors, facilitating removal by sessile macrophages lining the circulation. Under these circumstances, transit time is reduced by several fold (Igarishi et al. 1999; Zhang et al. 1999; Mittler et al. 1999).

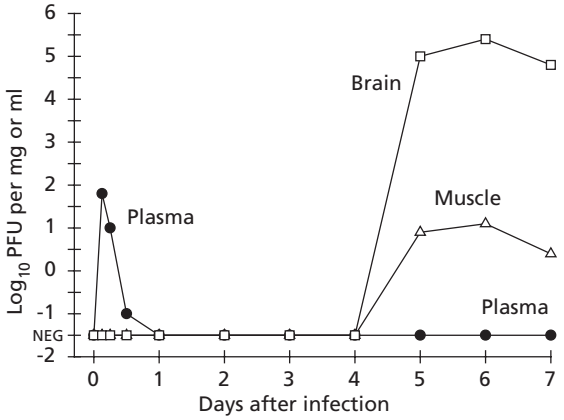

Figure 4 *Passive viremia, after injection of La Crosse virus in weanling mice. Viremia appears as a sharp peak limited to the first 12 h and stands out in profile since there is no active viremia in mice of this age. Even this transient viremia was sufficient to deliver enough virus to the target organ to initiate a lethal encephalitis (data from Pekosz et al. 1995).*

Although plasma viremias are usually shortlived, there are notable exceptions. Some viruses are bound by antibody, but the immune complex retains infectivity. In these instances, such as Aleutian disease virus (a parvovirus) and lactic dehydrogenase virus (a togavirus), plasma infectivity may resist neutralization with exogenous antibody but may be reduced by the addition of anti-Ig antibodies (Notkins et al. 1966; Porter and Larsen 1967). Other exceptions are instances where the infected host is tolerant of the viral antigens and fails to develop a sufficient level of antibody to clear viremia. Examples are hepatitis B virus and lymphocytic choriomeningitis virus (Figure 6).

A number of viruses replicate in cells that are found in the circulation, particularly monocytes, B or T lymphocytes, or (rarely) erythrocytes (Table 4). Under these circumstances, the viremia is cell-associated, although some virus may also be found free in the plasma compartment. Cell-associated viremias may be of short duration, as in the case of ectromelia and other poxviruses. However, in many instances of cell-associated viremia, virus titers are low, virus may be difficult to isolate from the blood, and viremia persists

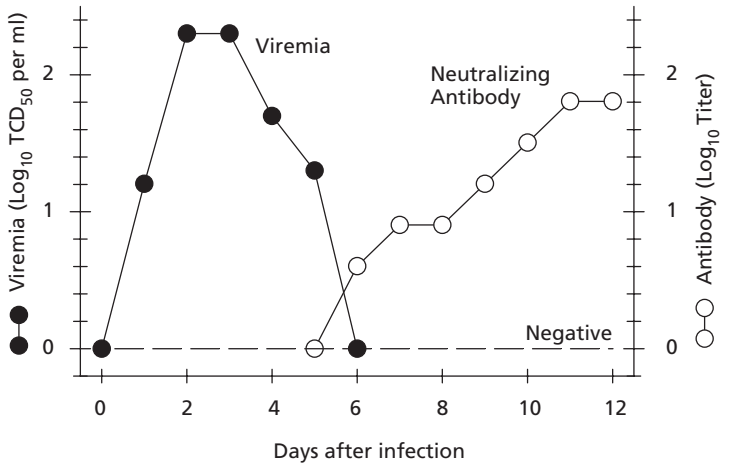

Figure 5 *Active plasma viremia after intramuscular injection of poliovirus in monkeys. Viremia lasts for about 1 week, and the clearance of viremia coincides with the appearance of neutralizing antibody in the serum (data from Nathanson and Bodian 1961).*

for the life of the host rather than terminating when neutralizing antibody appears (Figure 7).

Human immunodeficiency virus provides an important instance of cell-associated viremia (Hsia and Spector 1991; Bagasra et al. 1993; Levy 1998). HIV infects both $CD4^+$ T lymphocytes and monocytes in the blood, but most infected cells are $CD4^+$ T lymphocytes. The frequency of infected peripheral blood $CD4^+$ T lymphocytes varies from 0.2 to 10 percent in asymptomatic persons to between 2 and 60 percent in symptomatic patients, and 50–90 percent of infected T lymphocytes contain the genome in a latent state. In typical asymptomatic individuals, there are about 5 000 infected cells per ml blood. In addition to infected cells, free infectious HIV is also present in the plasma, the amount varying with the stage of disease. In typical asymptomatic individuals, it has been estimated that there are about 100 tissue culture infectious doses (TCD) per ml plasma, considerably fewer than the number of infected cells.

Antibody-dependent enhancement of infection is a special aspect of cell-associated viremia, which has been described mainly for dengue and other flaviviruses (Halstead and O'Rourke 1977; Gollins and Porterfield 1984). Dengue virus replicates primarily in monocytes, but it does not enter these cells readily. However, in the presence of low concentrations of antibody, infection is markedly enhanced, presumably because the virus–antibody complex is bound to Fc receptors on monocytes, enhancing viral entry.

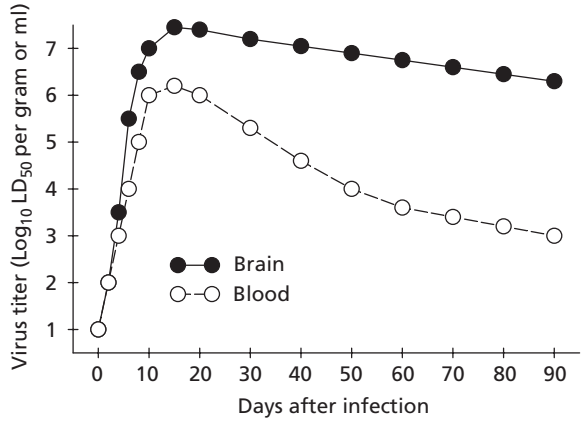

Figure 6 *Persistent plasma viremia associated with immunological hyporesponsiveness to the viral antigens. Adult mice were infected with lymphocytic choriomeningitis virus (LCMV) intracerebrally and were immunosuppressed with aminopterin on days 4 and 6 after infection. Mice infected in the same way but not treated with aminopterin died of acute choriomeningitis about 8 days after infection (data from Hotchin 1962).*

Tissue invasion from the blood

There are several ways in which a virus might cross the vascular wall (Johnson and Mims 1968; Johnson 1998), but the precise mechanism for penetrating the blood–tissue barrier is unknown in most instances.

- In many tissues, the capillary endothelial cells are not joined by tight junctions, and viruses can pass between them. One example is the fenestrated capillaries of the choroid plexus of the central nervous system. Penetration at this site provides access to the epithelial cells of the choroid plexus and can be followed by entry into the cerebrospinal fluid and spread to the ependymal cells lining the ventricles (Herndon et al. 1974).
- Virus may be transported through endothelial cells by a process of endocytosis, translocation of virus-containing vesicles, and subsequent release by exocytosis at the basal surface of the endothelial cell (Johnson and Mims 1968; Pathek and Webb 1974).
- Some viruses are capable of replicating within endothelial cells and are released from these cells into the surrounding tissues. Examples include selected picorna-

viruses, retroviruses, alphaviruses, and parvoviruses (Johnson 1965; Baringer and Nathanson 1972; Friedman et al. 1981; Pitts et al. 1987).

- Viruses that cause a cell-associated viremia may invade by an alternate mechanism, namely, as passengers in infected lymphocytes or monocytes, a mechanism that has been suggested for tissue invasion of HIV and other lentiviruses (Haase 1986). Infected mononuclear cells can cross the blood–tissue barrier as part of their normal trafficking pattern, or may be actively recruited into sites of inflammation.

NEURAL SPREAD

Some viruses can disseminate by spreading through the axons of peripheral nerves (Table 5). Although less

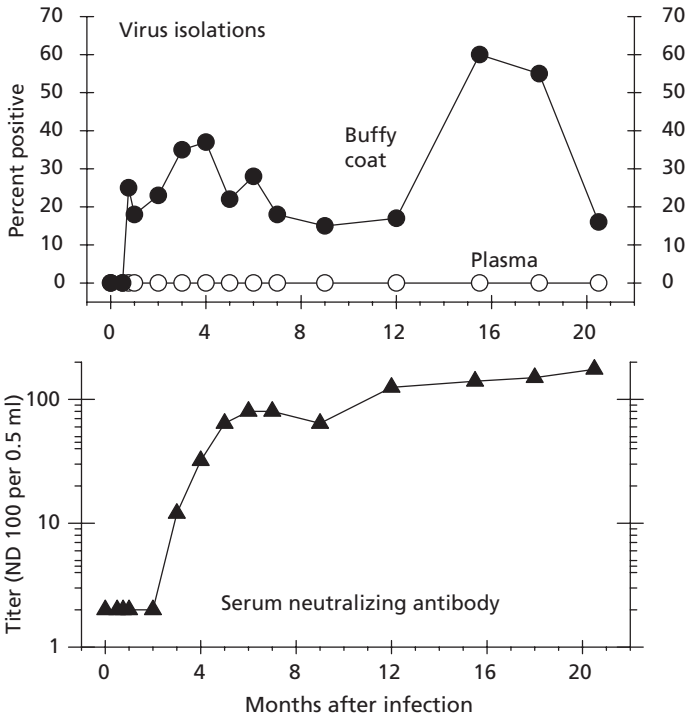

Figure 7 *Cell-associated viremia in sheep infected with visna maedi virus, a* Lentivirus*. Virus was isolated by cocultivation of buffy coat cells with indicator cells and was never isolated from the plasma. The frequency of virus isolations was unrelated to the appearance or titer of neutralizing antibody (data from Petursson et al. 1976).*

	Pseudorabies	Used for neural pathways	Enquist (1994)

Venezuelan equine encephalitis virus (VEE).

important than viremia, neural spread plays an essential role for certain viruses (such as rabies viruses and several herpesviruses), while other viruses (such as poliovirus and reovirus) can utilize both mechanisms of spread (Johnson 1998). Different strains of the same virus may differ markedly in their ability to use the neural route (Nathanson and Bodian 1961; Tyler et al. 1986; Ren et al. 1990; Barnett and Perlman 1993), as shown in Table 6. Also, different viral variants may utilize different neuronal pathways (Card et al. 1998).

It seems certain that viruses enter neurons by mechanisms similar to those involving entry into other cell types. The uncoated nucleocapsid is then carried passively along axons or dendrites, probably by fast axoplasmic flow (Maratou et al. 1998; Ohka et al. 1998). After the transport process, the virus may replicate in the perikaryon, but this is a much slower process and is not required for neural spread. There are several lines of evidence for this reconstruction of neural spread:

Table 6 *Different mode of dissemination of a neurotropic and a pantropic strain of the same virus*

	Neuroadapted MV strain		Pantropic Mahoney strain	
	Control	Block	Control	Block
Paralysis	25/26	0/11	19/19	18/20

Incubation to paralysis	5 days	–	7 days	7.5 days

Comparison of a neuroadapted and a natural pantropic isolate of poliovirus following intramuscular injection in cynomolgus macaques. The neuroadapted virus spreads only by the neural route, causes initial paralysis in the injected limb and fails to paralyse after a nerve block, while the pantropic strain spreads by viremia, does not cause localised initial paralysis, and is not impeded by nerve block. (Data from Nathanson and Bodian 1961).

- Neural transection will block neural spread (Table 6) and the rate of movement (>5 cm per day) is similar to the rate of axoplasmic transport (>10 cm per day) (Kristensson et al. 1971; Tyler et al. 1986; Tsiang 1993).
- Drugs, such as colchicine, which block fast axoplasmic transport by disrupting microtubules, also block the transport of viral genomes (Tsiang 1979).
- Temperature-sensitive strains of herpesvirus (which cannot replicate at body temperature) are able to move from a peripheral site of inoculation to a sensory ganglion, such as the trigeminal ganglion, and may be recovered by culturing the explanted ganglion at temperatures that are permissive for temperature-sensitive clones (Sederati et al. 1993).
- Several days after initiation of neural spread, the nucleocapsids of viruses, such as rabies virus, herpes simplex virus, and pseudorabies virus (an alphaherpes virus), may be seen within axons (Rabin et al. 1968).

Localization or tropism

One of the salient features that distinguishes viruses is their tropism within the animal host (see Figures 1 and 2). The names of individual viral diseases often reflects the organs or tissues that are involved. Thus, smallpox, poliomyelitis, and hepatitis each have their characteristic features. Localization of infection, or viral tropism, is regulated both by viral dissemination and cellular susceptibility. Disease localization may not correspond to the distribution of infection since it reflects both the spread of the virus and the host response to infection.

VIRAL DISSEMINATION

The localization of a virus is determined at several phases of infection, including penetration at the portal of entry, systemic spread by viremia or the neural route, and the invasion of local organs or tissues.

Portal of entry

The physical characteristics of a virus that influence its ability to survive in the external environment play a role in circumscribing the portal of entry. Thus, many picornaviruses are enteroviruses that are capable of surviving in the hostile environment of the enteric tract, but some picornaviruses, such as the rhinoviruses, are acid labile, cannot survive gastric acidity, and are confined to the respiratory tract. The biological characteristics of the virus also plays a role in its initial localization. Again, the rhinoviruses replicate well at 33°C, the temperature of the nasopharynx, while influenza virus has a replication optimum of 37°C that permits it to infect the lower respiratory tract. These limiting factors are particularly important for the localization of viruses that fail to spread systemically.

Viremia and neural spread

Viremia plays a key role in systemic spread of most viruses (Figures 1 and 2), and the viremogenicity of the specific viral strain determines its likelihood of reaching target organs. Conversely, the inability to initiate viremia explains the local nature of the infections caused by many respiratory and enteric viruses. The importance of viremia in determining localization is illustrated in Table 7, which indicates that in adult mice La Crosse virus (a bunyavirus) has the capability of initiating a lethal encephalitis after intracerebral injection of a minimal dose (approximately 1 plaque forming unit (pfu)), but fails to cause illness after subcutaneous injection of $>10^7$ pfu because no viremia is produced. Likewise, poliovirus, in spite of its high potential to induce paralysis, is estimated to cause only one paralytic case per 150 human infections, presumably because it rarely generates sufficient viremia to reach the spinal cord (Figure 8).

For viruses that spread primarily by the neural route, the ability to disseminate is also an important determinant of localization (Gromeier and Wimmer 1998). For instance, herpes simplex virus is capable of initiating a very severe encephalitis in humans if the virus reaches the central nervous system. However, most infections are either silent, or limited to mucocutaneous lesions, and encephalitis occurs at a rate of less than one case per 1 000 primary infections, indicating that the virus rarely reaches its potential target in sufficient dose to localize in the brain.

CELLULAR RECEPTORS

Most viruses are quite selective in the cell types that are infected in vivo and this selectivity plays a significant role in localization. One major determinant of cellular susceptibility is the presence of viral receptors, namely, molecules on the cellular surface that act as receptors for the specific virus, usually by binding a protein on the virion surface (the viral attachment protein). From studies of many viral receptors (Figure 9), several generalizations can be made (Wimmer 1994a; Dimitrov 2000):

- Although receptors have been identified for only a small proportion of viruses, it is generally thought that specific receptors are necessary for efficient infection by most viruses. Presumably viruses have evolved to utilize, as receptors, cellular surface molecules that subserve other functions required for normal cellular activity.
- A variety of molecules, including glycoproteins, glycolipids, and glycosaminoglycans, can serve as viral receptors. The domain of the receptor that binds the virus may be either a polypeptide sequence or a carbohydrate moiety, often located at the external tip of the receptor molecule.
- Different viruses employ different cellular receptors, although a few receptors are used by more than one virus.
- Many viruses are capable of utilizing more than a single cellular molecule as a receptor.
- Different isolates of the same virus may prefer different receptors, and a specific virus isolate may alter its receptor preference by selection of a mutant viral attachment protein during serial passage in animals or cell cultures (Borza and Hutt-Fletcher 2002).
- In some instances, viral entry requires two or more different coreceptors on the cell surface. Usually, both coreceptors are necessary and neither alone is sufficient.

Table 7 *The relative virulence of viruses depends on variables such as the route of entry and age of the host.*

	PFU per LD_{50}			
Virus clone	IC infection suckling mice[a]	SC infection suckling mice	IC infection adult mice	SC infection adult mice
Wild-type La Crosse original	~1	~1	~1	$>10^7$
Attenuated B.5 clone	~1	$>10^5$	$>10^6$	$>10^7$

Illustrated by two variants of La Crosse virus, a bunyavirus, when injected by different routes in suckling and adult mice. One clone, La Crosse/original, is a wild-type isolate and the other clone, B.5, is a laboratory-derived attenuated strain. Note that the two viruses exhibit striking differences in virulence upon intracerebral injection of adult mice or subcutaneous injection of suckling mice, but that both appear similar in their high virulence for suckling mice inoculated intracerebrally and similar in their low virulence for adult mice inoculated subcutaneously. Virulence is expressed as the ratio of pfu per LD_{50}; the lower the number the more virulent the virus. IC, intracerebral; SC, subcutaneous (data from Endres et al. 1990).

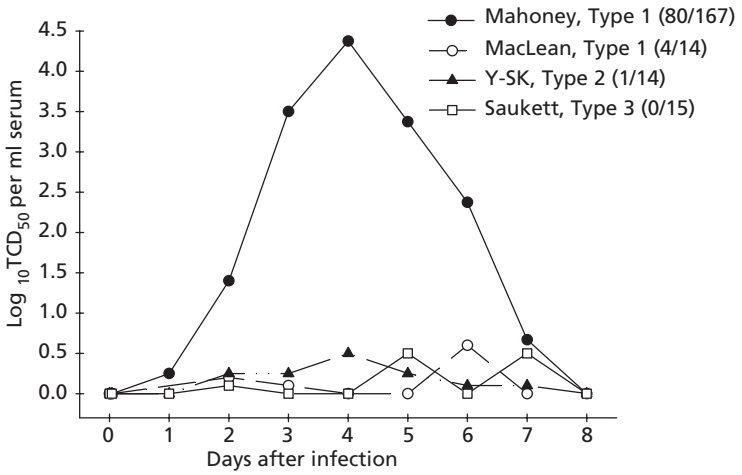

Figure 8 *Viremia as a determinant of viral virulence. Type 1 Mahoney virus produced the highest level of viremia and the highest frequency of paralysis (48%) while the other three (low viremia) strains produced an aggregate paralytic rate of 12% (the frequency of paralysis is shown in parentheses) (data from Bodian 1954).*

- Entry of a virus into a potential host cell is a multistep process in which binding to the receptor is only the initiating event.
- Not all cells that express the viral receptor are capable of supporting the complete cycle of viral replication.

These generalizations are illustrated by human immunodeficiency virus (HIV) (Levy 1998; Weiss 1994). The CD4 molecule is a type I glycoprotein, which is expressed by certain subsets of T lymphocytes and monocytes/macrophages, and subserves signaling between lymphoid and monocytic cells. CD4 has four immunoglobulin-like domains in its extracellular amino terminus, and the outermost of these domains contains a region that binds a specific site on gp120, the surface glycoprotein of HIV. The primary cellular targets of HIV are $CD4^+$ T lymphocytes and

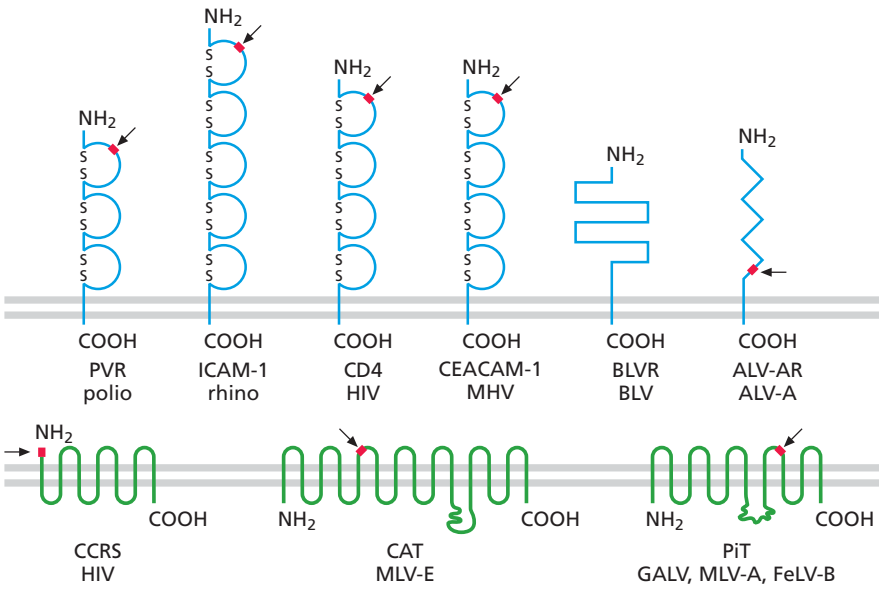

Figure 9 *Molecular backbone cartoons of some glycoprotein viral receptors. Receptors diverge widely in their structure and in their physiological function. The amino and carboxy termini are shown, together with important disulfide bonds and the probable domains that bind virus. ALV-AR, avian leukosis virus A receptor; BLVR, bovine leukemia virus receptor; CAT, cationic amino acid transporter; CCR5, chemokine receptor 5; CEACAM, carcinoembryonic antigen-related cell adhesion molecule; ICAM, intercellular adhesion molecule; PiT, inorganic phosphate transporter; PVR, poliovirus receptor; Viruses: polio, poliovirus; rhino, rhinovirus, major group; HIV, human immunodeficiency virus; MHV, mouse hepatitis virus (a coronavirus); BLV, bovine leukemia virus; ALV-A, avian leukosis virus A; MLV-E, murine leukemia virus E; GALV, gibbon ape leukemia virus; MLV-A: murine leukemia virus A; FeLV-B; feline leukemia virus B (after Wimmer 1994b; Weiss and Tailor 1995; Holmes, 1997).*

monocytes/macrophages and the distribution of CD4 explains this cellular localization.

However, the expression of CD4 on the surface of a cell is not sufficient to assure viral entry. HIV utilizes a coreceptor, several members of the family of chemokine receptors, most frequently CCR5 or CXCR4 (Berger et al. 1999). HIV-1 strains can utilize either CCR5 or CXCR4 or, in some instances, both coreceptors. CCR5 is expressed on macrophages, while CXCR4 is expressed on T-lymphocyte cell lines, explaining why some HIV-1 strains will infect macrophages but not T-cell lines, while the reverse is true for other HIV-1 strains (Figure 10). Furthermore, there are important biological distinctions between HIV-1 isolates that use R5 or X4 coreceptors. Under natural conditions, infections are mainly initiated by R5 viruses, while X4 viruses are more frequent in patients with advanced AIDS. In experimental infections of monkeys, R5 viruses preferentially infect lymph nodes while X4 viruses replicate preferentially in gut-associated lymphoid tissue (Harouse et al. 1999).

Poliovirus offers another example of localization determined by receptors (Wimmer et al. 1994; Freistadt 1994; Evans and Almond 1999). It was long known that poliovirus would only replicate in primate tissues, and it had been deduced that this was because a putative poliovirus receptor (PVR) was expressed only by primate cells, since nonprimate mammalian cells would support poliovirus replication if transfected with viral RNA, thereby bypassing the requirement for a viral receptor. Using this conceptual framework, the PVR was cloned and sequenced, and when transfected into rodent cells it rendered them permissive for the virus (Mendelsohn et al. 1989). Furthermore, when transgenic mice were created that expressed the PVR, the animals developed typical clinical and pathological poliomyelitis after intracerebral injection of human poliovirus (Ren et al. 1990).

However, the relationship of the PVR to viral localization appears to be more complex, since the PVR alone may not confer cellular susceptibility. Thus, the PVR is expressed quite ubiquitously in human tissues, but most of these tissues are not infected by the virus. Also, PVR transgenic mice cannot be readily infected by the oral route (the natural route of infection in primates) and pantropic strains of poliovirus that are viremogenic in primates fail to cause viremia in these mice (Ren and Racaniello 1992).

OTHER MECHANISMS OF CELLULAR LOCALIZATION

Cellular susceptibility may be determined at post-entry steps in the replication cycle. Some viruses are quite fastidious and can replicate only in selected cell types, thus accounting for their selective tropism. For example, some of the murine leukemia viruses appear to require enhancers or promoters that are supplied only in certain cell types (Evans and Morrey 1987). In these instances, genetic studies have mapped the viral determinants of replication to the unique 3′ (U3) noncoding region of the viral genome (Hopkins et al. 1989).

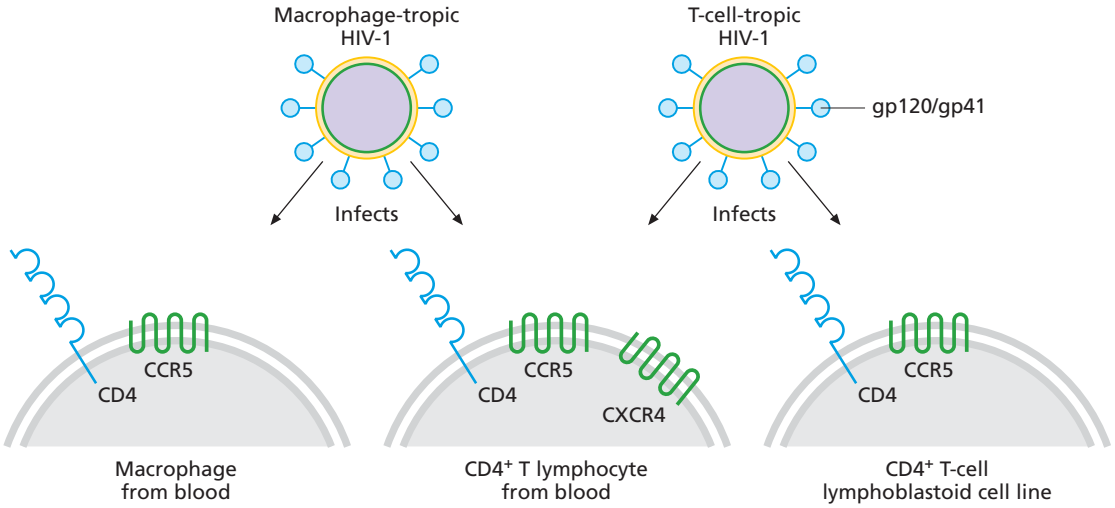

Figure 10 *HIV-1 is an example of a virus that requires a primary receptor and a coreceptor to infect target cells efficiently. The primary receptor is the CD4 molecule, a protein expressed on the surface of certain subsets of lymphocytes (so called CD4⁺ cells). The gp120 spike glycoproteins of all HIV strains can bind to human CD4. In addition, virus entry requires a coreceptor, which is either CCR5 or CXCR4. These proteins are members of a large family of molecules that serve as chemokine receptors on the surface of lymphoid cells or macrophages. Some HIV-1 isolates are macrophage-tropic because their gp120 spikes use CCR5, a chemokine receptor that is expressed on the surface of macrophages, while other isolates are T-cell-tropic because they utilize the CXCR4 molecule, another chemokine receptor expressed on the surface of T-cell lines. Both kinds of viruses can replicate on peripheral blood mononuclear cells (PBMC), lymphocytes freshly cultured from peripheral blood, since these cells express both coreceptors. By the same token, some HIV-1 isolates (not shown) are dual-tropic since they can utilize both coreceptors. (Recent studies have shown that macrophages express low levels of CXCR4 at concentrations insufficient for entry of T-cell-tropic HIV-1.)*

A number of enveloped viruses encode glycoproteins that require cleavage to activate either their viral attachment function or their fusion function. Absent proteolytic cleavage virions are not infectious. An example is Newcastle disease virus, a paramyxovirus of birds. Virulent isolates of Newcastle disease virus encode a fusion protein that is readily cleaved by furin, a proteolytic enzyme present in the Golgi apparatus, so that the protein is activated during maturation prior to reaching the cell surface, and before budding of nascent virions. This makes it possible for virulent strains of the virus to infect many avian cell types, thereby increasing its tissue host range, and causing systemic infections that are often lethal. In contrast, avirulent strains of Newcastle disease virus encode a variant fusion protein that is not cleaved during maturation in the Golgi, so that nascent virus requires activation by an extracellular protease. The required protease is found only in the respiratory or enteric tracts, thereby limiting tropism to surface cells and conferring an attenuated phenotype on the virus (Nagai 1995).

LOCALIZATION OF VIRAL PATHOLOGY

Pathological lesions were traditionally used to trace the spread of viral infections. However, the pathological process initiated by viral infections does not always co-localize at the sites of viral replication. Some viruses kill all cells in which they replicate and, in such instances, viral disease tends to mirror the localization of viral replication. In contrast, certain viruses will destroy some, but not all, of the cells in which they replicate. For instance, viruses that are cytocidal because they trigger a cascade of events leading to cellular apoptosis may replicate in a noncytodical fashion in cells in which apoptosis is blocked by the protective effect of the bcl-2 proto-oncogene (Griffin et al. 1994).

A number of viruses initiate immune-mediated cellular pathology in which $CD8^+$ T lymphocytes attack cells that present viral peptides associated with MHC class I proteins. If the virus infects both cells that do and do not express MHC class I molecules, then the MHC negative cells are not attacked. This phenomenon is thought to explain the sparing of neurons after infection by certain viruses, since neurons do not express class I molecules (Rall et al. 1995). Immune-mediated lesions may be even more indirect, such as those that are caused by antigen–antibody complexes. In this instance, the lesions are seen in locations such as the glomerulus of the kidney, which cannot handle the large accumulations of macromolecular complexes, while the virus has replicated at sites distant from the kidney (Oldstone 1975). Dengue hemorrhagic fever is thought to be initiated by the antiviral immune response that leads to a consumptive coagulopathy (Rothman and Ennis 1999).

For oncogenic viruses, the tumors may represent a distant echo of virus localization (Figure 11).

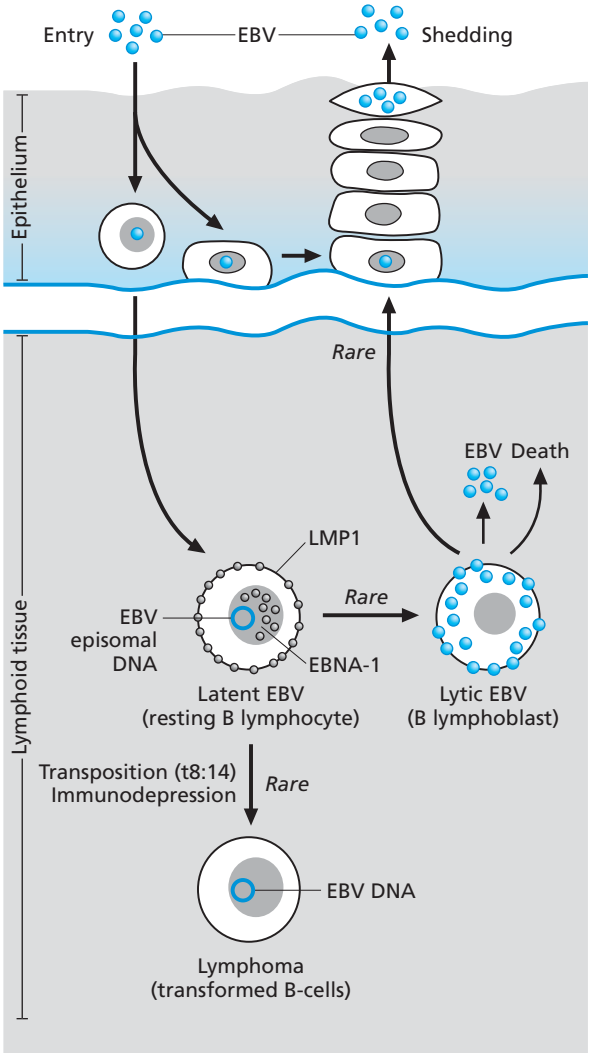

Figure 11 *The localization of pathological lesions may only be a remote echo of the distribution of the causal virus, as exemplified by this diagrammatic summary of possible pathogenesis of EBV and Burkitt's lymphoma. The virus initially infects epithelial cells and B lymphocytes. In epithelial cells, EBV causes both latent and lytic infection, the latter resulting in virus shedding into the oral cavity. EBV persists in resting B cells as a latent infection which is rarely activated to produce new virus. During latent persistence in lymphocytes, several EBV genes are expressed, particularly EBNA-1 (EB nuclear antigen) and LMP1 (latent membrane protein) which immortalizes B cell clones. In a few infected people, persistently infected B cells undergo further transformation into tumor cells, producing a variety of lymphomas, such as Burkitt's lymphoma, which is frequently associated with a chromosomal transposition (t8:14) that up-regulates the* c-myc *oncogene (after Nathanson et al. 2002).*

Epstein–Barr virus (EBV) infects epithelial cells and B cells (Burkitt 1958; Epstein et al. 1964; Hutt-Fletcher 1999; Cohen 2000). EBV causes both a latent and a lytic infection in epithelial cells from which it is shed into the oral cavity. Latently infected B cells are immortalized, and – rarely – these B cells undergo further transforma-

tion into lymphomas by virtue of additional genetic events such as chromosomal transposition (t8:14). Lymphoma cells often carry EBV DNA as nuclear episomes.

Shedding

Acute viral infections are characterized by brief periods of intensive virus shedding into respiratory aerosols, feces, urine, or other bodily secretions or fluids. Persistent viruses are often shed at relatively low titers, but this may be adequate for transmission over the prolonged duration of infection.

GASTROINTESTINAL AND RESPIRATORY TRACT

The course of shedding of enteric viruses can be readily followed. For instance, poliovirus is shed in the pharynx for 2–4 weeks and in the feces for 1–2 months after infection, although viremia only lasts about 1 week (Figure 5). Respiratory viruses may be transmitted by aerosols generated by coughing or sneezing or by virus-containing nasopharyngeal fluids that are transmitted by hand-to-hand contact. Most acute respiratory viruses are excreted over a relatively short period and infected persons are potential transmitters for only about 1 week (Figure 12). Transmission may begin a few days before onset of symptoms (Douglas et al. 1966).

SKIN, MUCOUS MEMBRANES, ORAL AND GENITAL FLUIDS, SEMEN, AND MILK

Although many viruses replicate in the skin, relatively few are spread from skin lesions. Exceptions are herpes simplex (labial transmission), varicella-zoster (rarely spread from zoster to cause chickenpox), papillomaviruses, and Ebola virus, a filovirus which causes hemorrhagic fever (Peters 1997). Those viruses, such as herpes simplex type 2 and papillomaviruses, which cause sexually transmitted disease, are often shed from lesions of the genital mucous membranes. In addition, some viruses, such as rabies virus and mumps virus, replicate in the salivary glands and are discharged into the saliva to enter the oral cavity.

Several viruses are shed in the semen, including hepatitis B and human immunodeficiency virus (Alter et al. 1977; Levy 1998). A number of viruses are excreted in colostrum and milk, including cytomegalovirus, mumps, rubella, and ovine visna maedi virus (de Boer and Houwers 1979) and HIV.

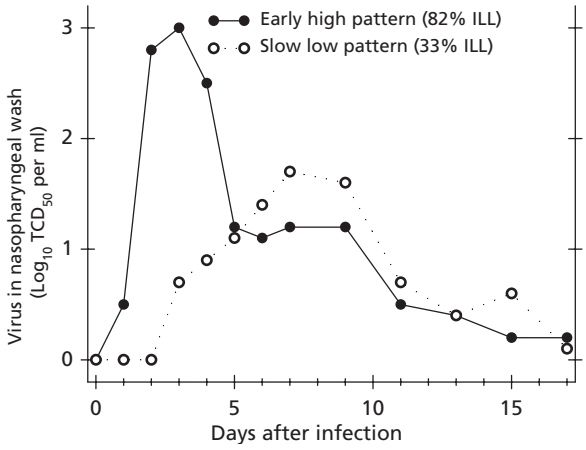

Figure 12 *The excretion of a typical respiratory virus, rhinovirus type 15, following inoculation of human volunteers by the transnasal route. The subjects demonstrated either an early onset high concentration pattern associated with a high frequency of respiratory symptoms, or a late onset low concentration pattern associated with a low frequency of symptoms (data from Douglas et al. 1966).*

BLOOD AND URINE

Blood is also an important source of transmitted virus, particularly for those viruses that produce persistent plasma or cell-associated viremias. Hepatitis B, C, D viruses, human immunodeficiency virus, HTLV-1, HTLV-2, and cytomegalovirus are among the important human pathogens shed in this manner. Arboviruses usually cause short-term acute viremias, and are transmissible only if an appropriate vector ingests a blood meal during this brief interval. In view of the limited amount of blood taken, the viremia must reach considerable levels if it is to be transmitted.

A number of viruses have been isolated from the urine, but viruria is probably not important for transmission of most viruses. A special exception are certain zoonotic viruses, such as the arenaviruses and the hantaviruses, which cause lifelong virurias in their natural rodent hosts, leading to human infection through exposure to aerosolized dried urine (Gonzalez-Scarano and Nathanson 1990). Cytomegalovirus spreads readily among young children in enviroments contaminated by urine (such as creches and play centers).

SURVIVAL IN THE ENVIRONMENT

The probability that a virus will be transmitted depends both upon the intensity and duration of shedding, and upon its ability to survive in the environment. Viruses differ in their ability to survive in aerosols and, somewhat surprisingly, under conditions of low humidity, enveloped viruses appear to be better able to retain viability than do nonenveloped viruses (deJong and Winkler 1968). To be excreted in an infectious form, enteric viruses must survive the harsh environment of the lower gastrointestinal tract.

Transmission

Once shed, there are several means by which a virus is transmitted from host to host in a propagated chain of infection. Probably the most important mechanism

is contamination of the hands of the infected transmitter from feces, oral fluids, or respiratory secretions expelled during coughing or sneezing. The virus is then passed by hand-to-hand contact leading to oral, gastrointestinal, or respiratory infection. A second common route is inhalation of aerosolized virus. A third significant mechanism involves direct person to person contact (oral–oral, genital–genital, oral–genital, or skin–skin). Finally, indirect person-to-person transmission can occur via blood or contaminated needles. Common source transmissions are less frequent but can produce dramatic outbreaks, via contaminated water, food products, or biologicals, such as blood products and vaccines.

The success of a virus, as a life form, can be defined as its ability to be perpetuated over the millenia. In turn, perpetuation of a virus depends in part upon its efficient transmission, particularly for viruses that cause only acute infections. The relative transmissibility of a virus in different populations is reflected in the age-specific profile of immune individuals, as illustrated in Figure 13 for hepatitis A virus. For viruses that can persist in individual hosts, perpetuation is determined by transmission over the lifetime of the host, and in some instances, by the ability to be vertically passed to offspring of the host, either by transplacental or perinatal routes, or as germline genes. If transmissibility is reduced sufficiently, then a given virus will disappear from a defined population. This can happen in nature, when a virus spreads so widely in a specific population that it eliminates most susceptibles and burns out. Transmissibility can also be reduced by immunization which, under certain circumstances, can be used to eradicate a virus from its host population. Smallpox is the seminal example of planned eradication (Fenner et al. 1988), and the elimination of wild poliovirus from the western hemisphere is another important illustration.

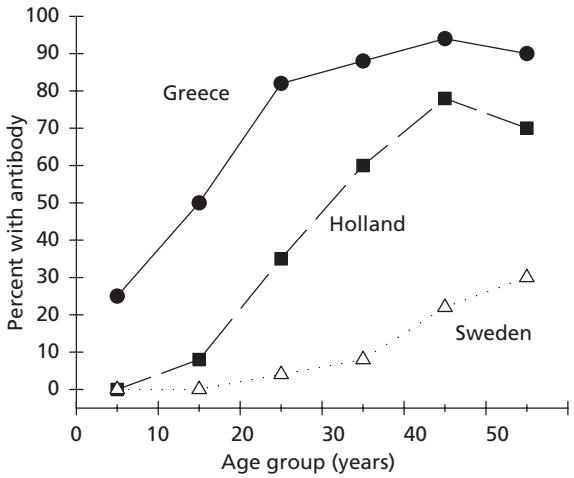

Figure 13 *Differences in transmissibility of hepatitis A virus in three European countries, as reflected in the different age-specific profiles of antibody prevalence (data from Frosner et al. 1979).*

VIRULENCE OF VIRUSES

Virulence refers to the ability of a virus to cause illness or death in an infected host, relative to other isolates or variants of the same agent. From the beginning of experimental virology, it has been recognized that different strains of a given virus may vary in their ability to cause disease. The study of virulence variants can provide important insights into pathogenesis, and variation in viral phenotype must be given consideration in design and interpretation of in vivo studies of the dissemination, localization, and pathological consequences of viral infection. Study of virulence also has practical implications because it carries the potential for development of attenuated live virus variants that can be used as vaccines, a principle that was initially recognized by Jenner in 1798 when he introduced vaccinia virus for the prevention of smallpox (Fenner et al. 1988).

There are two distinct approaches to the study of virulence. If virulence is regarded as a property of the virus, it is possible to map the genetic determinants that underlie the virulence phenotype. The other approach to virulence is through a study of pathogenesis, which describes the differences in infections with viral variants of different virulence. Pathogenic measures of virulence may be quantitative, involving the rate of viral replication or number of cells infected. Alternatively, differences in virulence may be qualitative, since variants of a single virus may differ markedly in their cellular tropism, their mode of dissemination in the infected host, or the disease phenotype that they produce.

Measures of viral virulence

RELATIVE NATURE OF VIRAL VIRULENCE

Virulence is not an absolute property of a virus strain but depends upon the dose of virus, the route of infection, and the age, gender, and genetic susceptibility of the host. Two viruses that differ in virulence in one experimental paradigm may exhibit similar degrees of virulence in another paradigm. This point is illustrated in Table 7, which compares a virulent wild-type clone with a laboratory-derived attenuated clone of California serogroup bunyaviruses. When the two viruses are injected intracerebrally in adult mice, the differences in their virulence are striking. One plaque forming unit (pfu) of the wild-type virus will initiate a fatal encephalitis, whereas 10^6 pfu of attenuated clone B.5 fails to cause any illness. On the other hand, both viruses are highly virulent when injected intracerebrally in suckling mice (approximately 1 plaque-forming unit (pfu) of either virus is lethal) and cannot be distinguished.

CLINICAL, PATHOLOGICAL, AND FUNCTIONAL INDICATORS OF DISEASE

The conventional measure of viral virulence is the production of disease in the host, using as an endpoint either death or some specific constellation of signs and symptoms caused by the infection. This is illustrated in Table 8, which compares the paralytic rate following primary infection with wild-type virus versus the rate following oral poliovirus vaccine. An alternative measure of virulence is an assessment of virus-induced pathological lesions. Also, laboratory tests, that reflect virus-induced pathophysiological changes, can be used as surrogate markers of virulence. For instance, the severity of hepatitis can be assessed by the serum titer of alanine aminotransferase that signals release of hepatocellular proteins, and the severity of human immunodeficiency virus infection by the reduction in the the blood concentration of $CD4^+$ T lymphocytes.

For a precise estimation of virulence, it is important to adjust for virus dose, which can conveniently be done by titrating different virus strains in a permissive cell culture system, as well as in animals. The ratio of plaque forming units per 50 percent lethal dose (pfu per LD_{50}) can then be compared for different virus variants (Figure 14).

Experimental manipulation of virulence

A prerequisite to the study of virulence is the availability of viral variants differing in their virulence phenotype. In some instances natural isolates may differ in virulence, for instance, serotype 1 and serotype 3 reoviruses, which vary remarkably in their biological properties even though reassortants between them are readily constructed. In many instances, laboratory manipulation must be used to obtain virulence variants.

PASSAGE IN ANIMAL HOSTS

In general, passage by a defined route in a particular species enhances the virulence of the virus when assessed under the conditions of passage, but often reduces the virulence in other animals or by alternate routes of infection. Human polioviruses on occasion have been adapted to mice; repeated mouse passage of monkey neurovirulent isolates produces variants that often have high intracerebral and intraspinal virulence for mice, but may exhibit relatively low intracerebral virulence for monkeys (Racaniello 1988).

PASSAGE IN CELL CULTURE

Passage in cell culture frequently leads to the selection of attenuated virus strains. A prominent example was Theiler's successful search for an attenuated variant of yellow fever virus, culminating in the selection of the 17D strain (Theiler and Smith 1937). Experience with cell passage has led to several common observations: (1) apparently identical passage protocols can yield stocks with different degrees of attenuation so that there is an element of unpredictability in this approach to attenuation; (2) viral stocks often represent a swarm of genetically diverse variants that differ in their degree of attenuation; and (3) attenuated variants may be temperature sensitive even when they were not selected for this phenotype.

MUTAGENESIS AND TEMPERATURE-SENSITIVE MUTANTS

A standard strategy for the production of attenuated variants is the treatment of a virus with a mutagen. One convenient way to select mutants is to look for viral variants that are temperature sensitive (ts), and that will replicate well at the permissive temperature of 33–37°C, but not at an elevated nonpermissive temperature, such as 40°C, where the nonmutagenized parent virus will still replicate well. Many ts mutants have reduced virulence in animals. Reduced virulence is not necessarily a direct consequence of temperature sensitivity, since the body temperature of the host is frequently within the range of permissive temperatures. It is more likely that such ts mutants are also host range restricted in certain cell types even at the permissive temperature, thus explaining their in vivo attenuation. Although random mutagenesis is a convenient way to produce attenuated viruses, it has the drawback that there may be mutations in several viral genes that are silent in cell culture, but influence the in vivo phenotype, complicating conclusions about the mechanism of attenuation.

Many viruses can be cold adapted by passage at a reduced temperature (traditionally 25°C) and such variants are often attenuated in animals (Maassab and DeBorde 1985). Cold-adapted variants of influenza virus replicate as well at 37°C and much better at 25°C than wild-type virus, but are usually temperature sensitive at

Table 8 *Virulence expressed as the comparative ability of different strains of a virus to produce clinical illness*

Virus	Paralytic case rate per 1 000 000 primary infections (range)	Relative rates	Study period
Wild-type (mainly type 1)	7 000 (2 000–20 000)	~10 000	1931–1954
OPV (mainly type 3)	0.62	1	1961–1978

The paralytic rate following infection with wild-type polioviruses is compared to the rate following infection with attenuated oral polioviruses (OPV). Data from Schonberger et al. 1976; Nathanson and Martin 1979; Nathanson 1984; Nkowane et al. 1987.

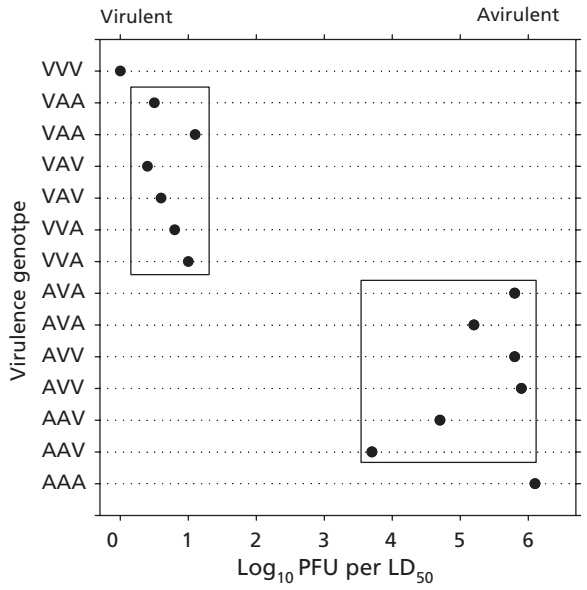

Figure 14 *Quantitative comparison of virulence using a panel of California serogroup viruses. Virulence is expressed as the ratio of plaque forming units per 50% lethal dose (pfu per LD_{50}) plotted on a log scale. Reassortants were made between a virulent (genotype VVV for the large, intermediate, and small gene segments, respectively) and an avirulent clone (genotype AAA). Reassortants bearing a large gene segment derived from the virulent parent had a virulent phenotype and those bearing a large segment derived from the avirulent parent had an avirulent phenotype (data from Griot et al. 1994).*

40°C, and have markedly reduced pneumopathogenicity when tested intranasally in ferrets. Cold-adapted influenza viruses have mutations in many or all of their eight gene segments, but reassortant viruses bearing only a few segments from cold-adapted variants exhibit the cold-adapted attenuated phenotype.

DESIGNED MUTATIONS

With the development of methods for introducing mutations into DNA, it has become possible to design mutants of many DNA and RNA viruses. Several different kinds of mutations can be introduced, including point mutations that result in substitution of a single or several individual amino acids, construction of genetic chimeras between two viral variants by exchange of genetic sequences, or inactivation of an open reading frame either by introduction of a stop codon, insertion of a selectable marker cassette, or deletion of part of the open reading frame. In some instances, noncoding domains of the viral genome carry major determinants of virulence, which can be mapped by similar methods (Almond 1991; Minor 1993; Racaniello et al. 1993).

An example of the use of these methods is provided by human and simian immunodeficiency viruses (HIV and SIV), where genetic modifications have been utilized to address various aspects of virulence (Levy 1998). For instance, chimeric viruses have been used to map macrophage tropism to the *env* gene and point mutations have been used to map tropism within the fine structure of the V3 loop of the gp120 envelope protein. Introduced stop codons and deletions have been used to explore the role of the *nef* gene of SIV, with the finding that *nef* deletions do not affect the ability of the virus to replicate in cell culture, but markedly reduce the ability of a virulent clone, mac 239, to induce AIDS in rhesus monkeys (see below).

SELECTION OF ATTENUATED VARIANTS

In selecting variants of reduced virulence, several points should be kept in mind. First, as noted above, most virus pools consist of a mixture of variants, which may differ markedly in their biological phenotype. Thus, it is necessary to plaque purify and characterize a number of stocks prior to selecting virus variants for study. Secondly, the mutations of greatest interest are those that specifically impair virulence in vivo without affecting the ability of a virus to replicate in a defined reference cell culture system. Such mutants can be considered to be 'host range' variants in contrast to 'global' mutants that impair replication in all cell hosts.

With the development of panels of monoclonal antibodies for most viruses, it has become possible to select variants that escape neutralization. Such variants often represent point mutations and occur naturally at a frequency of about 10^{-5} depending on the virus (Steinhauer and Holland 1987). When a panel of such monoclonal antibody-resistant (MAR) variants are tested in vivo, it is often observed that a few of the escape mutants are attenuated. Variants selected in this manner generally have mutations in the viral attachment protein since this is the typical target of neutralizing monoclonal antibodies.

Pathogenic mechanisms of virulence

There are many sequential steps in a viral infection and a difference in the comparative replication of two virus variants at any one of these steps could explain their relative degrees of virulence. In practice, attenuated variants will usually replicate or spread less briskly in one or several tissues associated with the pathogenic process. Also, variant viruses may differ qualitatively in their cell and tissue tropism or in their mode of dissemination.

VIREMIA

A reduction in viremia can be an important mechanism for the reduction in virulence. An example is shown in Figure 8 that compares poliovirus strains of different virulence. The Mahoney strain of type 1 poliovirus caused a much higher viremia and paralytic rate than did several other strains that were less viremogenic.

NEURAL SPREAD

Rabies viruses are obligatory neurotropes and disseminate only by neural spread. The attenuation of rabies virus has been investigated using MAR mutants. Some of the MAR variants in one epitope group were markedly attenuated, and one attenuating mutation was mapped to a single amino acid residue (at position 333) in the rabies glycoprotein (Tuffereau et al. 1989). After intramuscular injection, an attenuated mutant spreads to the brain at a rate similar to virulent parent CVS virus, but within the central nervous system the attenuated clone spreads to relatively few neurons, while the virulent virus spreads rapidly to many contiguous neurons (Jackson 1991). The difference between virulent and attenuated MAR viruses lay in their differential efficiency of entry into neuronal cells, probably associated with differences in the binding of their glycoproteins to cellular receptors (Dietzschold et al. 1983).

TROPISM AND HOST RANGE

Different variants of a single virus can exhibit differences in their tropism for organs, tissues, and cell types, which confers a multidimensional character upon virulence. Thus, a variant virus may be reduced in its ability to cause one type of pathology but enhanced in its ability to cause another. Human immunodeficiency virus (HIV) presents an example of tropism differences (Table 9). Most strains of HIV can be classified into two categories, according to their ability to replicate in T-cell lines (T-tropic) or in primary macrophages (M-tropic) (Levy 1998). Tropism has been mapped to the V3 domain on the envelope glycoprotein (gp120) and is associated with coreceptor preference. HIV utilizes members of the chemokine receptor family as a co-receptor. M-tropic viruses preferentially utilize CCR5 while T-tropic viruses preferentially utilize CXCR4 as a coreceptor. Most viruses isolated shortly after infection are M-tropic, while most viruses isolated from patients with severe AIDS are T-tropic. It is inferred that M-tropic viruses are preferentially transmitted for reasons yet to be elucidated, while T-tropic viruses replicate preferentially in T lymphocytes, particularly in patients lacking immune defenses.

VIRULENCE FOR TARGET ORGANS

Different variants of a specific virus may show different degrees of virulence for a key target organ. The three attenuated strains of poliovirus used in the oral poliovirus vaccine provide an example (Table 10). The type 3 strain has the greatest virulence since it causes more cases of paralytic poliomyelitis in vaccine recipients than does either the type 1 or type 2 strains. The type 2 strain is clearly the most viremogenic in children. However, after intracerebral injection of monkeys, the type 3 strain produces very severe spinal cord lesions at a higher frequency than do the type 1 or type 2 strains. In this instance, virulence for the target organ (the spinal cord), rather than viremogenicity, appears to be the most important determinant of virulence after virus feeding.

TUMORIGENESIS

When applied to tumor viruses, virulence can be expressed in several different ways. The most common differences among the oncogenic viruses involve either the latent period from infection to development of a neoplasm, or the cell type that is transformed. In general, the transforming retroviruses can be divided into two major classes, according to whether they cause tumors with a long latency or are acutely transforming. The long latency viruses are often replication competent and do not carry a transduced oncogene. They act as insertional mutagens when their proviruses are integrated into the host DNA. On rare occasion, insertion occurs at a site where the promoter, enhancer, or terminator sequences in the viral genome can influence the transcriptional rate of a proto-oncogene. Up-regulation of such a proto-oncogene then leads to transformation of the infected cell, which can result in neoplasia usually after a long latency.

Murine leukemia viruses (MuLV) are replication-competent long latency oncogenic retroviruses. Different MuLV isolates induce different kinds of neoplasms, involving T lymphocytes, B lymphocytes, erythroid, or myeloid precursor cells. Genetic studies, including the production of viral chimeras, has mapped the genetic determinants to the viral U3 region, a

Table 9 *Isolates of a single virus may vary in their host range*

		Growth in each cell type		
Viral biotype	**HIV-1 isolate**	**Peripheral blood T lymphocytes**	**Monocyte-derived macrophages**	**T cell line Sup-T1**
T-tropic	IIIB	++++	+	++++
	DV	++++	++	++++
M-tropic	SF162	++++	+++	–
	89.6	++++	+++	–

HIV (human immunodeficiency virus) strains can be classified into two major biotypes, M-tropic (replicating in macrophages) and T-tropic (replicating in T-lymphocyte cell lines) as shown for several different virus strains.
Data from Collman et al. 1989; Collman and Nathanson 1992.f

Table 10 *Virulence for the target organ appears to be the major determinant of the relative in vivo virulence of the three oral poliovirus vaccine strains.*

	Type 1	Type 2	Type 3
In vivo virulence (poliomyelitis in OPV recipients)	22	13	62
Viremogenicity (frequency of viremia)	0/16	17/19	0/16
Neurovirulence (percent severe lesions)	0.05%		1.15%

Top line. The type 3 vaccine strain causes paralytic poliomyelitis at a rate that is about threefold higher than the type 1 and fivefold higher than the type 2 strain. Cases of paralytic poliomyelitis in recipients of oral poliovirus vaccine (OPV), United States, 1961–1984. Data from Schonberger et al. 1976; Nkowane et al. 1987.
Middle line. The type 2 strain generates viremia more effectively than either of the other strains indicating that it has a much higher potential for invading the spinal cord. Frequency of viremia in infants fed oral poliovirus vaccine. Data from Horstmann et al. 1964.
Bottom line. On direct intraspinal injection of monkeys, the type 3 strain causes severe spinal cord lesions at a rate that is much higher than the rate associated with the type 1 strain. Data from Nathanson and Horn 1992.

noncoding part of the viral genome that is just upstream from the transcriptional start site and has a domain that contains a number of transcriptional enhancer sites (Hopkins et al. 1989). Tropism is thought to correlate with relative ability to replicate in different target cells, and this has been borne out, at least in part, by in vivo studies of the relative replication rates of different MuLVs in different tissues (Evans and Morrey 1987).

Genetic determinants of virulence

Viral virulence is encoded in the viral genome and expressed through structural proteins, nonstructural proteins, or noncoding sequences. A large body of information about virus variants has established several important points:

- The use of mutants has made it possible to identify the role of individual genes and proteins as determinants of the biological behavior of many viral variants.
- There is no 'master' gene or protein that determines virulence, and attenuation may be associated with changes in any of the structural or nonstructural proteins, or in the noncoding regions of the genome.
- The virulence phenotype can be altered by very small changes in the genome, if they occur at 'critical sites.' At such sites, a single point mutation leading to the substitution of a specific amino acid or base is often sufficient to alter virulence. For most viruses with small genomes (<20 kb) only a few discrete 'critical sites' have been discovered, usually fewer than 10 per genome.
- It is possible to create variants with attenuating mutations at several critical sites and these may be more attenuated than single point mutants. Also, reversion to virulence is less frequent in variants with several discrete attenuating mutations.
- Attenuating mutations are often host range mutations that affect replication in some cells, but not in others. This is partly a reflection of the fact that most well characterized mutants have been deliberately selected because they replicate well in a standard cell culture system.
- Although many attenuating mutations have been sequenced, relatively few have been characterized at a biochemical or structural level as to their mechanism of action.

These generalizations may be illustrated with examples from a few selected virus groups.

POLIOVIRUSES

Polioviruses are single-stranded RNA viruses of positive polarity, with a genome that contains a relatively long 5′ and a shorter 3′ nontranslated region (NTR) flanking a single open reading frame of about 7 kb that encodes a single polyprotein that is cleaved into four structural proteins (VP1-VP4) and several nonstructural proteins.

Virulence studies have focused on the three attenuated strains of types 1, 2, and 3 poliovirus that constitute the oral poliovirus vaccine (OPV) originally developed by Sabin (1985). The three vaccine strains are about 10 000-fold less virulent than wild-type poliovirus (Table 8), and they can be compared to the wild-type viruses from which they were derived. However, the genomes of wild-type parental viruses and their vaccine progeny differ at a considerable number of sites (reflecting their complex passage history) and many of these differences are not relevant to the attenuated phenotype. Virulent revertants of the vaccine strains occur on passage in humans or in cell culture and are better suited to genetic analysis, since there are relatively few sequence differences between them and the vaccine strains. Using reverse genetics (Racaniello and Baltimore 1981), infectious DNA clones of poliovirus genomes can be used to construct chimeric viruses and these clones can then be transfected into permissive cells to reconstitute mutated infectious virus.

The 5′ nontranslated region (NTR)

The attenuation of the vaccine strains of poliovirus is due to critical sites, both in the 5′ NTR upstream from the long open reading frame and in selected structural

and nonstructural proteins (Racaniello 1988; Minor 1992, 1993; Racaniello et al. 1993). Each of the three strains of OPV carry point mutations in the 5′ NTR, at positions 480, 481, or 472, in types 1, 2, and 3, respectively. Attenuating mutations at these sites are associated with reduced neurovirulence in monkeys, and reduced ability to replicate in the central nervous system of transgenic mice bearing the poliovirus receptor. Attenuated variants are temperature-sensitive host range mutants that replicate well in primate fibroblast cell lines, such as HeLa cells, but have reduced ability to replicate in neuroblastoma cells (La Monica and Racaniello 1989). The bases at attenuating sites in the 5′ NTR are thought to be involved in an RNA stem loop based on computer models of their predicted secondary structure. It is believed that the stem structure at positions 470–540 is involved in the binding of ribosomal complexes at the initiation of translation. Presumably, initiation factors must differ, either quantitatively or qualitatively, in different cell types to explain the cellular host range restriction of the vaccine strains.

Structural or nonstructural proteins

Each of the OPV strains carries at least one mutation that is associated with an alteration in a viral structural or nonstructural protein and confers temperature sensitivity and reduced neurovirulence, and these mutations involve different proteins for the three OPV strains. For type 1 OPV, mutations associated with increased virulence are found in the virus capsid proteins, and in the nonstructural 3D polymerase (Bouchard et al. 1995; Georgescu et al. 1995). For type 2 OPV, it appears that neurovirulence in the mouse is associated with virus capsid protein VP1 (Ren et al. 1991; Macadam et al. 1993). For type 3 OPV, sites in virus capsid proteins VP3 and VP1 confer temperature sensitivity and neuroattenuation (Tatem et al. 1992). It is not clear how mutations in the structural proteins produce attenuation, but it has been suggested that these are involved in structural transitions that occur either during virion assembly or virion uncoating.

BUNYAVIRUSES

Bunyaviruses are negative-strand (or ambisense) RNA viruses with a trisegmented genome. The large (L) RNA segment encodes the viral polymerase; the middle (M) RNA segment encodes two glycoproteins (G1 and G2) and a nonstructural protein, Ns_m; the small (S) segment encodes the nucleoprotein (N) and a nonstructural protein, Ns_s. Most studies of virulence have utilized members of the California serogroup that will reassort readily with each other. Beginning with two parent viruses, panels of reassortants containing all possible combinations of gene segments can be constructed. In addition, monoclonal antibody-resistant (MAR) mutants have been used to identify variants in the major G1 glycoprotein that are associated with differences in virulence. Attenuation can involve either the ability of the virus to replicate in the central nervous system (neurovirulence) or its ability to cause viremia and reach the central nervous system (neuroinvasiveness).

The middle RNA segment and glycoprotein G1

A detailed comparison has been made of two California serogroup viruses, wild-type La Crosse virus and a laboratory passaged strain of Tahyna virus which exhibited reduced neuroinvasiveness, but high neurovirulence (Griot et al. 1993a). The reduction in neuroinvasiveness of the attenuated virus is associated with low viremogenicity that, in turn, is associated with a reduced ability to replicate in striated muscle, the major extraneural site of replication of this group of viruses. Attenuation maps to the M RNA segment encoding the viral glycoproteins suggesting that there is an alteration in the entry phase of infection of myocytes (but not of neurons). These viruses plaqued equally well on BHK-21 cells. However, on a murine myocyte cell line (C2C12), viral variants bearing the M RNA segment of the attenuated parent failed to plaque while variants bearing the M RNA segment of the virulent parent plaqued well (Griot et al. 1994).

MAR mutants of La Crosse virus are readily obtained, using antibodies directed against the major (G1) glycoprotein, and a mutant at one epitope site (but not at other sites) exhibited reduced neuroinvasiveness with wild-type neurovirulence (Gonzalez-Scarano et al. 1985). Furthermore, the attenuated clone showed strikingly reduced fusion efficiency at acid pH compared to parental wildtype La Crosse virus. These observations suggested that attenuation might be associated with an alteration in glycoprotein G1 that reduced efficiency in the infection of myocytes.

The large RNA segment and the viral polymerase

An attenuated California serogroup virus clone, B.5, obtained by passage in BHK-21 cells, showed a striking reduction in its ability to replicate in the central nervous system of adult mice. Using reassortant analysis (Figure 14) clone B.5 was shown to bear an attenuated L RNA segment (Endres et al. 1990). This clone is a temperature-sensitive host range mutant that replicates poorly in C1300 NA neuroblastoma and other murine cell lines, although it grows well in BHK-21 cells. Presumably, clone B.5 has a mutant polymerase that restricts viral replication in neurons and certain other cell types.

REOVIRUSES

Reoviruses are double-stranded ten-segmented RNA viruses. The gene segments and the proteins that they

encode have been characterized in detail. The large number of segments have made reoviruses an attractive model system for study of the genetic determinants of viral phenotypes (Virgin et al. 1997). These studies have been facilitated by major differences in the biological phenotypes of naturally occurring reovirus serotypes, particularly serotypes 1 and 3. Table 11 illustrates the use of reassortants to map virulence phenotypes to reovirus gene segments.

Biological functions have been ascribed to many of the reovirus genes and proteins. Most of the virulence determinants represent qualitative differences between type 1 Lang and type 3 Dearing (T1L and T3D) in tissue and organ tropism rather than quantitative differences in disease severity.

- The S1 segment encodes the σ1 protein, which is the viral attachment protein that binds to receptors on permissive cells, and is a major target for neutralizing and hemagglination inhibiting (HI) antibodies. T1L and T3D viruses differ markedly in the disease that they cause in suckling mice. T1L disseminates through the blood and causes an ependymitis in the brain, while T3D disseminates through the neural route and causes a neuronotropic encephalitis in the brain. The S1 segment is the major determinant of dissemination and brain cell tropism (Table 11). In addition, the S1 segment is a determinant of replication in cardiac myocytes and myocarditis, of replication levels in the intestine, and of differences in reovirus strains to induce apoptosis and perturb the cell cycle.
- The M1 segment encoding the μ2 protein influences replication in cardiac myocytes and myocarditis.
- The M2 segment encoding the μ1 protein affects the protease sensitivity of the virion, and quantitative neurovirulence.
- The L1 segment encoding λ3 protein influences replication in cardiac myocytes and myocarditis.
- The L2 segment encoding λ2 protein acts as a guanylyl transferase in cell culture and influences replication levels in the intestine, titers of shed virus, and horizontal transmission between mice.

Viral virulence genes of cellular origin

Since 1985 a new class of virus-encoded proteins has been recognized that contribute to the virulence of viruses by mimicking normal cellular proteins (McFadden 1995). This group of 'cell-derived' genes has been identified primarily within the genomes of large DNA viruses that probably have a greater capacity to maintain accessory genes than do viruses with small genomes. Because these genes are homologues of cellular genes, it is hypothesized that they were acquired by recombination and modification. Thus, from an evolutionary viewpoint, they resemble viral oncogenes.

Cell-derived viral genes encode proteins that enhance virulence by many different mechanisms. 'Virokines' are secreted from virus-infected cells and mimic cytokines, thereby perturbing normal host responses. 'Viroceptors' resemble cellular receptors for cytokines (including antibodies or complement components) that are thereby diverted from their normal cellular targets. Some virus-encoded proteins interfere with antigen presentation and

Table 11 *Mapping virulence to a specific viral gene segment*

	Outer capsid gene segments			Core gene segments					Nonstructural gene segments		
Pattern of spread	M2	S1	S4	L2	L1	L3	M1	S2	M3	S3	Clone
Viremia	L	L	L	L	L	L	L	L	L	L	T1L
	D	L	L	L	L	L	L	L	D	D	R
	L	L	L	D	D	D	D	D	L	D	R
	L	L	D	L	L	L	L	L	L	L	R
	D	L	D	D	D	D	D	D	D	D	R
	D	L	L	D	D	D	L	D	D	D	R
	D	L	D	D	D	D	D	D	L	D	R
Neural	D	D	D	D	D	D	D	D	D	D	T3D
	D	D	D	D	D	D	D	D	D	L	R
	L	D	L	L	D	L	L	L	L	L	R
	L	D	L	L	L	L	L	L	L	L	R
	L	D	L	D	L	L	L	L	L	L	R

The *S1* gene segment of reovirus determines whether the virus spreads by viremia or by the neural route, since it was the only gene segment that cosegregated with the mode of spread. Two viruses, type 1 Lang (T1L) and type 3 Dearing (T3D) were used to derive reassortant clones (R) that were genotyped (L or D indicates origin of each gene segment) and were tested for their mode of spread.
Adapted from Tyler et al. 1986.

immune induction (Smith et al. 1997; Lafon 2002; Jackson and Ramsay 2001), while others prevent apoptosis or interrupt intracellular signalling initiated by cytokines or interferons. A brief review of selected cell-derived genes that have been described for pox and herpes viruses will serve as examples of this group of viral genes and illustrate how they contribute to viral virulence.

POXVIRUSES

Tumor induction

Several poxviruses cause either benign or malignant tumors. However, it appears that the mechanism of oncogenesis is different from that associated with classic DNA or RNA tumor viruses, since there is no evidence that viral sequences are incorporated into the genome of transformed cells. Virus strains may gain or lose tumorigenicity quite independent of their ability to replicate, and continued productive replication of the virus appears to be required for tumor growth. It was postulated in the 1960s that these viruses might produce a growth factor that accounted for their induction of tumors (Kato et al. 1963). A large body of research has now documented that several poxviruses encode a protein that can be classified as a member of the epidermal growth factor (EGF)-like family of growth factors (McFadden et al. 1995). Shope fibroma virus and malignant rabbit fibroma virus both encode a very similar protein (Shope fibroma growth factor (SFGF)), while myxoma virus encodes a related myxoma growth factor (MGF). These proteins contain the shared functional domains (six characteristically spaced cysteines) shared by members of the EGF family. Furthermore, when these genes are deleted from the virus genomes, the MGF-negative or SFGF-negative viruses replicated normally in cell culture, but showed much reduced ability to induce tumors in rabbits (Opgenorth et al. 1992).

Receptors for tumor necrosis factor

Tumor necrosis factor (TNF) is a potent pro-inflammatory cytokine that is produced by activated macrophages and T cells. TNF acts by binding to a class of cellular receptors that are type 1 integral membrane proteins characterized by multiple cysteine-rich exodomains. Through their receptors on myeloid and lymphoid cells, the TNFs exert complex pleiotropic effects on immune networks and host responses to infection. A number of poxviruses encode a protein designated T2 that is a soluble form of the cellular p75 TNF receptor (Smith and Goodwin 1995). It is presumed that this protein binds free TNF, thereby modulating TNF-mediated cellular responses to infection. It is postulated that T2 could enhance replication of poxviruses in vivo by down-modulating the antiviral defenses of the infected host, although T2 might simultaneously favor the host by reducing the severity of virus-induced inflammatory lesions.

Vaccinia virus complement control protein (VCP)

The complement system is a complex group of proteins that act in a cascade that forms one of the initial host defenses against microbial pathogens. The system is a potent one that, uncontrolled, has the potential to cause severe damage, and is therefore tightly regulated by several different mechanisms, including C4-BP, a plasma protein that binds C4b2a, one of the complexes formed in the course of complement activation. Vaccinia virus encodes a protein, vaccinia virus complement control protein or VCP, that is homologous to C4-BP (Isaacs and Moss 1995). VCP binds human C4b and a VCP– mutant of vaccinia virus fails to inhibit complement-mediated lysis of sensitized sheep erythrocytes, while wild-type vaccinia virus has an inhibitory effect (Kotwal et al. 1990). When wild-type and VCP– vaccinia viruses were compared in vivo, the VCP– mutant was less virulent upon intracerebral injection of mice and, as shown in Figure 15, produced smaller skin lesions after intradermal inoculation in rabbits (Isaacs et al. 1992).

HERPES SIMPLEX VIRUSES

Herpes simplex virus (HSV) complement receptors

The importance of the complement cascade and its regulation already have been mentioned. C3b, one of the intermediates in the cascade, plays a key role in initiating the formation of the membrane attack complex (the last part of the complement cascade) so that its regulation is important. A number of cell types,

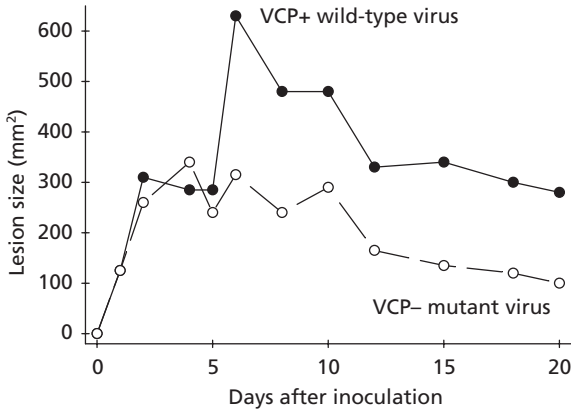

Figure 15 *Cell-derived viral genes can act as virulence factors. The skin lesions (median of three rabbits) produced by a wild-type vaccinia virus expressing the vaccinia complement control gene (VCP+) are more extensive than the lesions caused by the same virus from which the gene had been deleted (VCP–) (data from Isaacs et al. 1992).*

including monocytes/macrophages, neutrophils, and some T cells, express receptors for C3b, that down-modulate the complement cascade by reducing the levels of C3b and enhancing its inactivation by cleavage to iC3b. Glycoprotein C (gC) of HSV-1 binds C3b and iC3b, thereby providing protection against complement-mediated neutralization of HSV, and against complement-mediated lysis of HSV-infected cells (Harris et al. 1990; York and Johnson 1995). Although it has not yet been demonstrated that gC− mutants are less virulent in vivo, the conservation of gC in natural isolates of HSV suggests that this protein (and its complement-binding activity) play a role in HSV survival in nature.

HSV Fc receptors

HSV-infected cells express receptors (FcR) for the Fc domain of the immunoglobulin (IgG) molecule (Baucke and Spear 1979). A considerable body of work (York and Johnson 1995) has identified glycoproteins gE and gI of HSV as the molecules that bind IgG. It has been suggested that the presence of Fc receptors on the HS virion or on the surface of virus-infected cells would lead to bipolar bridging of the IgG molecule that might reduce secondary effects of antibody binding, such as the ability to initiate the complement cascade. Comparison of an FcR-deficient mutant, expressing an altered gE protein, with wild-type HSV, has shown that FcR-deficient virus is more susceptible to complement-mediated neutralization and lysis of virus-infected cells, as shown in Figure 16 (Frank and Friedman 1989; Dubin et al. 1991). Furthermore, gE− HSV exhibits reduced virulence in mice (Rajcani et al. 1990).

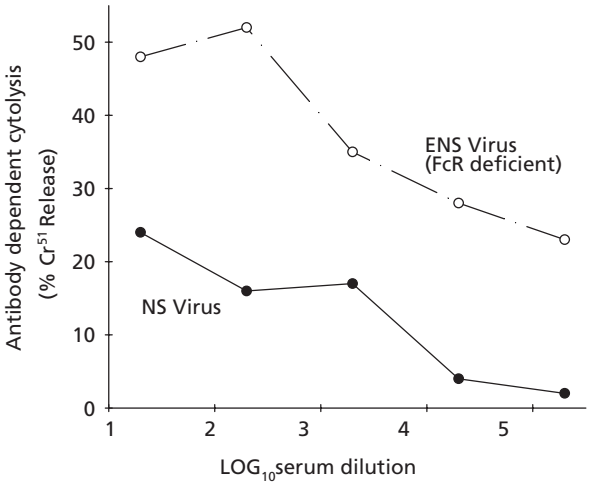

Figure 16 *Cell-derived viral genes can act as virulence factors. Glycoprotein gE of herpes simplex virus, which functions as an Fc receptor (FcR), influences the susceptibility of HSV-infected cells to antibody-dependent cell-mediated cytotoxity (ADCC). Target cells infected with the NS (FcR+) strain of HSV show lower percent lysis than cells infected with an FcR-deficient mutant of NS virus (strain ENS), indicating that the viral-encoded FcR can reduce the susceptibility of HSV-infected cells to ADCC (data from Dubin et al. 1991).*

PERSISTENT INFECTIONS

A number of viruses are capable of producing infections that persist for the lifetime of the host (Ahmed and Chen 1999). In order to persist, a virus must achieve a delicate balance such that it maintains its genome without killing the host. In addition, the virus must evade immune surveillance mechanisms that are sufficiently potent to be able to clear many acute viral infections (Ploegh 1998).

Immune clearance of acute virus infections

If the duration of an acute infection is defined as the time between acquisition of infection to total clearance, then length ranges from about 1 week (for rhinoviruses) to about 6 months (for hepatitis B virus). Before considering immune evasion, it is useful to recapitulate briefly the mechanisms by which the immune response eliminates an acute infection. Effector T lymphocytes with specificity for the antigenic determinants of an infecting virus can destroy virus-infected cells, produce antiviral cytokines, such as interferon, and recruit phagocytic cells to the sites of infection. B lymphocytes differentiate into plasma cells that secrete antiviral antibodies which can neutralize virions, initiate complement-mediated virolysis, and opsonize virus so that it is efficiently phagocytosed (Figure 5) (Binder and Griffin 2001). To persist, a virus must evade these mechanisms (Igarishi et al. 1999).

Mechanisms of persistence

Many different genera of both RNA and DNA viruses include members that can cause persistent infections. Furthermore, the same viruses may cause either acute self-limited or persistent infections, depending upon the circumstances of infection. Lytic viruses that kill the cells in which they replicate tend to use different strategies than nonlytic viruses that can be shed from cells over long periods of time without cell death. The strategies of persistence can be classified into three major categories, which are outlined in Figure 17. For each viral strategy, there is a corresponding strategy for evasion of the immune response.

- *High titer replication* requires that virus either be noncytocidal or that there is rapid replacement by cellular proliferation of target cells. Immune surveillance is unable to eliminate the virus, due to tolerance, immune complex formation, viral mutation, or another mechanism.
- *Latency* requires that the viral genome can persist in a nonreplicating mode, either integrated into the

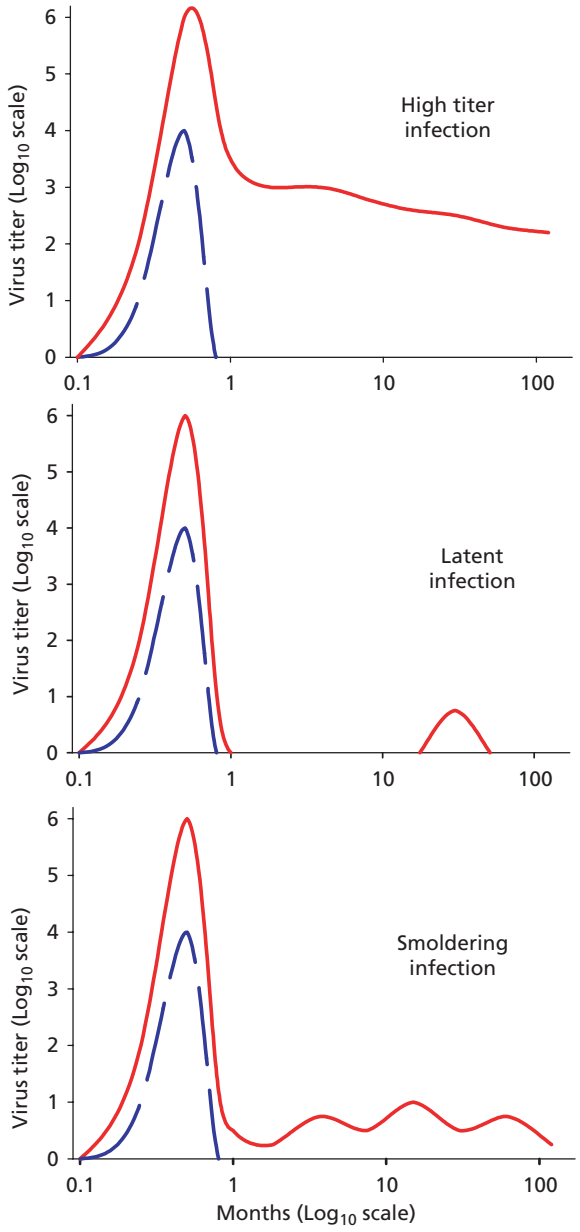

Figure 17 *Patterns of virus persistence. For reference, an acute infection is shown by dashed line in all panels.* High titer infection*: An acute phase is often apparent, following which the titer drops but persists at a high level for a long time.* Latent infection*: An acute infection is followed by disappearance of replicating virus which persists only as a latent genome. Periodic recrudescence occurs, during which replication of the virus may be accompanied by signs of disease, followed by another period of latency. Intervals between recrudescences may last from weeks to many years, and some infected individuals may never experience a recrudescence.* Smoldering infection*: An acute infection of varying severity is followed by marked reduction in overt virus replication, but infectious virus may be frequently recovered indicating that true latency has not occurred (after Nathanson et al. 2002).*

genome of the host cell or as an episome. Immune surveillance may be competent to eliminate the virus which can be activated but can only replicate for brief intervals. Alternately, recurrence may be associated with intermittent reduction of immune defenses.

- *Smoldering infections* involve continuous productive infection and cell-to-cell transmission at a low level. Usually, potentially effective immune surveillance is circumvented by mechanisms such as antigenic variation, infectious immune complexes, or intercellular bridges.

HIGH-TITER PERSISTENT INFECTIONS

Nonlytic viruses

Many viruses can replicate productively without causing cell death, and a number of them can cause persistent infections. In such instances, the initial dynamics resemble those of an acute infection, following which the virus titer decreases somewhat, but then reaches a setpoint that may be maintained indefinitely or gradually decline. Examples of this pattern are hepatitis B virus HBV and lymphocytic choriomeningitis virus (LCMV) of mice (Buchmeier and Zajac 1999).

High-titer persistence is often characterized by tolerance, an apparent absence of virus-specific immunity. The mechanisms by which the tolerance can be induced include deletion of forbidden clones of naive T lymphocytes in the thymus and exhaustion of peripheral virus-specific T lymphocytes in the presence of excess antigen. Tolerance may be limited to specific components of the effector limb of the immune response. For instance, hepatitis B virus persistence is characterized by absence of antiviral antibody against HbsAg while anti-HBcAg may be induced. LCMV persistence is characterized by absence of cellular immune responses while virus-specific antibody is produced. The presence of persistent high titers of virions and viral antigens may overwhelm either antibody or $CD8^+$ lymphocytes, so that assays must be interpreted with caution. Thus, in persistently infected mice, anti-LCMV antibodies circulate as immune complexes and not as free antibody, which originally led to the mistaken view that antibody was not induced in persistently infected mice.

Evidence for the role of immune tolerance in maintaining viral persistence is provided by the experimental termination of persistence by intravenous injection of virus-specific $CD8^+$ cells. Figure 18, summarizing an experiment with LCMV, exemplifies this phenomenon. Similar results have been obtained with HBV, where CTLs specific for HBs epitopes cleared virus from hepatocytes.

Lytic viruses

It is unusual for high titer persistence to be produced by a cytolytic virus, but the primate lentiviruses represent an important exception. Figure 19 shows the persistent viremia produced by simian immunodeficiency virus (SIV). The main target cells for these lentiviruses are

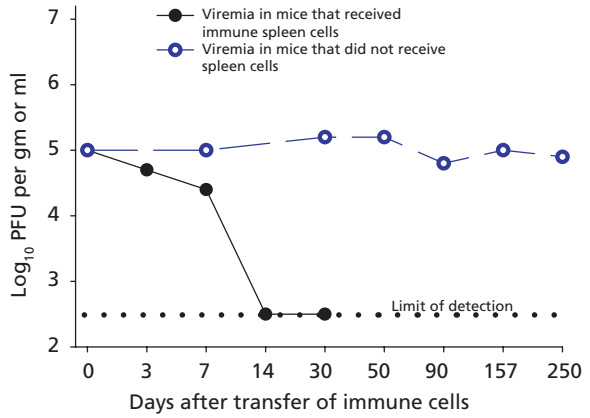

Figure 18 *Immune T lymphocytes can clear a persistent virus infection, implying that (in some instances) persistence involves escape from the cellular arm of the immune response. In this example, LCMV causes persistent lifelong infection of mice. When such mice are treated by adoptive immunization of CTLs from an immune donor ($10^{7.3}$ spleen cells from adult mice immunized by infection 60 days prior to transfer), the virus is cleared. The specificity of the process is shown by the requirement for syngeneic donor lymphocytes and by the ability of clones of CD8$^+$ T lymphocytes specific for an individual viral epitope to clear infection. The rate of clearance differs for different organs and tissues, implying some differences in the action of effector cells and in the mechanisms of immune evasion (after Ahmed et al. 1987).*

CD4$^+$ lymphocytes which undergo lytic infection. It has been calculated that the continuous destruction of CD4$^+$ cells results in a reduction of the average half-life of these cells from 75 to 25 days. However, the bone marrow is able to respond to the abnormal rate of destruction by increasing the production of naive CD4$^+$ cells, at a rate sufficient to maintain a reasonable concentration of circulating CD4$^+$ cells. The compensatory replenishment of target cells permits this generally lytic virus to persist at a high titer for an extended period of time, although eventually the bone marrow is unable to compensate and CD4 levels drop, leading to functional immunodeficiency.

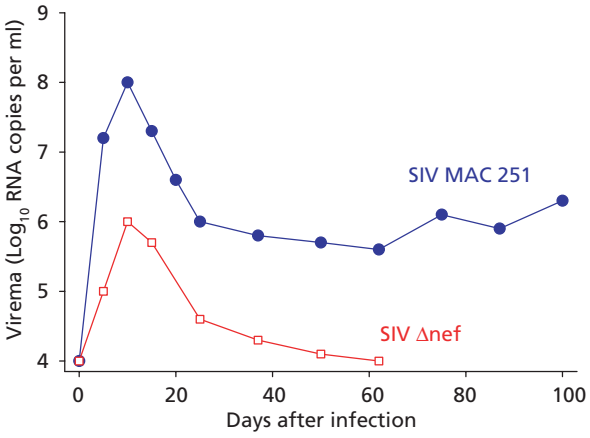

Figure 19 *Viral genes that influence immune clearance can alter in vivo infection. SIV mac 251 wildtype is compared with a mutant engineered to delete the* nef *gene, a regulatory gene that reduces expression of MHC class I molecules on the plasma membrane, permitting escape of virus-infected cells from immune attack. The figure shows the typical course of viremia in individual animals infected with wild-type and Δnef viruses (after Connor et al., 1998).*

In contrast to most high-titer persistent infections, lentiviruses induce immune responses rather than tolerance. The immune response to lentiviruses is quite effective, as judged by its ability to rapidly contain the acute phase of infection, resulting in a reduction from peak viremia at about 6 weeks to a setpoint at about 3–6 months which may be as much as 1 000-fold lower than the peak viremia. Once this setpoint is reached, a dynamic equilibrium is established between virus production and clearance. The half-life of individual SIV virions is <30 min in the absence of immunity and about 10 min in infected animals with an established immune response. It has been calculated that to maintain virus titers of 10^2 to 10^4 infectious virions per ml plasma requires the production of 10^{10} to 10^{12} new infectious virions daily. In this instance, high titer persistence is maintained by an extraordinary rate of virus production that exceeds the rate at which a potent immune response can clear the virus.

LATENCY

Latent infections are produced by a considerable number of herpesviruses, including herpes simplex viruses (HSV), varicella-zoster virus (VZV), Epstein–Barr virus (EBV), and cytomegalovirus (CMV) of humans. There is a characteristic sequence of events following primary infection. Initially the virus replicates in permissive cells at the portal of entry. The virus is lytic and destroys permissive target cells. Once immune induction has occurred, the virus is cleared and appears to be eliminated.

However, the viral genome persists in a latent form. Latency occurs in one or more cell types – such as neurons – that are distinct from the permissive cell types that support productive lytic infection. Neurons appear to be restrictive or permissive, depending upon their physiological state (Stevens 1994). Under conditions of restriction, the virus undergoes the early steps of entry and uncoating, but further steps in replication are blocked. In the absence of active replication, the viral genome is maintained in one of several forms, depending upon the specific virus and host cell. In some instances, the double-stranded DNA genome integrates into the host genome, while in other examples the genome persists as a non-integrated episome, in the nucleus or cytoplasm.

If latency occurs in cell types such as neurons that do not divide, then there is no need to replicate the latent genome. If the latent genome is maintained in dividing cells, then the genome must be replicated or it will be

diluted to extinction. If the genome is integrated into the host genome then it will be automatically replicated during the cell cycle. Episomal DNA can also be replicated by the enzymes involved in copying cellular genomes. However, there are no parallel mechanisms for RNA, so RNA viruses cannot assume a latent state unless they undergo reverse transcription to DNA intermediates. Latent viral genomes can be detected by in situ polymerase chain reaction (PCR) methods that – at their most sensitive – can detect as little as one genome per infected cell.

Latency maintains the viral genome for the lifetime of the infected host. Activation of latent infections occur at irregular intervals, and may never occur in some infected individuals. Activation of latent genomes can be initiated by a number of stimuli, characteristic for each virus. For instance, herpes simplex virus (HSV) can be activated by fever, sunburn, and trigeminal nerve injury. Most of these stimuli appear to act upon the primary sensory neurons in which latent HSV genomes are maintained. However, on occasion, waning of the immune response can serve as a trigger for activation of some herpesviruses.

Following reactivation of HSV, the viral genome may be transported by axoplasmic spread in both centripetal and centrifugal directions. Centrifugal spread, toward the periphery, conducts the virus to the skin where it may replicate and spread, causing herpes labialis (fever blister or cold sore). After spreading for a few days, host defenses prevent further spread, and the skin lesion heals. Centripetal spread from the trigeminal ganglion conducts the HSV genome to the central nervous system, where, in some instances, it can spread to cause an encephalitis that may be devastating.

Typically, viruses that cause latent infections induce a brisk and potent immune response that clears the initial infection. However, latently infected cells do not express viral proteins, permitting escape from immune surveillance. Furthermore, when the latent infection is activated, immune surveillance limits its spread. Latent viruses cannot be spread from host to host, but virus produced during activation may be spread to another host. For instance, activation of latent varicella zoster virus (VZV) produces characteristic skin lesions in older adults. Seronegative children exposed to virus aerosolized from these lesions can develop chicken pox, the primary form of VZV infection.

SMOLDERING INFECTIONS

Smoldering infections fall between the extremes of high titer persistence and latency. Infectious virus is produced, but at minimal levels that may require special methods for detection and isolation. Virus continues to spread from infected to uninfected cells, but often at an indolent tempo. If the virus is pathogenic, it may produce a gradually progressive chronic disease (McCune 2001). There is a detectable immune response to the virus and, in some instances, the response may be hypernormal, due to the continuous presence of viral antigens. The ability of a virus to spread in the presence of a potentially effective immune response is a paradoxical phenomenon, and involves a variety of strategies several of which may operate in any given example (Billeter et al. 1994; Cattaneo et al. 1987). Some of the more important strategies are described below.

Immunologically privileged sites

There are a few organs and tissues that favor virus persistence, particularly the brain and kidney. The brain has classically been considered an immunologically privileged site because immunological effector mechanisms may spare cells bearing foreign antigens if these cells are located in the brain (in contrast to foreign cells in other sites). There are at least two factors that account for virus persistence in the brain. First, the blood–brain barrier limits the trafficking of lymphocytes through the brain and, secondly, neurons express little if any MHC class I molecules rendering them relatively poor targets for virus-specific cytolytic T lymphocytes (CTL).

The kidney is the other tissue that frequently harbors persistent viruses, such as JC and BK polyomaviruses, and cytomegalovirus. Also, LCMV is cleared more slowly from the kidney than from other tissues, even the brain. However, there is no clear explanation why virus in the kidney should be able to evade immunological surveillance, although it has been speculated that lymphocytes may not readily cross the subendothelial basement membrane to access infected glomerular epithelial cells.

Intercellular bridges

In some instances, the process of entry of viruses into cells can be shortcircuited, so that a transient intercellular bridge is formed. Intercellular bridges permit the viral genome to pass from cell to cell without having to survive in the extracellular environment (Figure 20), thus providing a means of avoiding neutralizing antibody. This phenomenon is probably operative in a progressive fatal disease called subacute sclerosing panencephalitis (SSPE). In SSPE a defective variant of measles or rubella virus spreads gradually from neuron to neuron in spite of extraordinarily high titers of neutralizing antibody in the extracellular fluid of the brain parenchyma (Cattaneo et al. 1987; Billeter et al. 1994).

Suppression of MHC class I expression

A number of viruses, including adenoviruses and lentiviruses, encode specific proteins that are capable of down-regulating the expression of MHC class I mole-

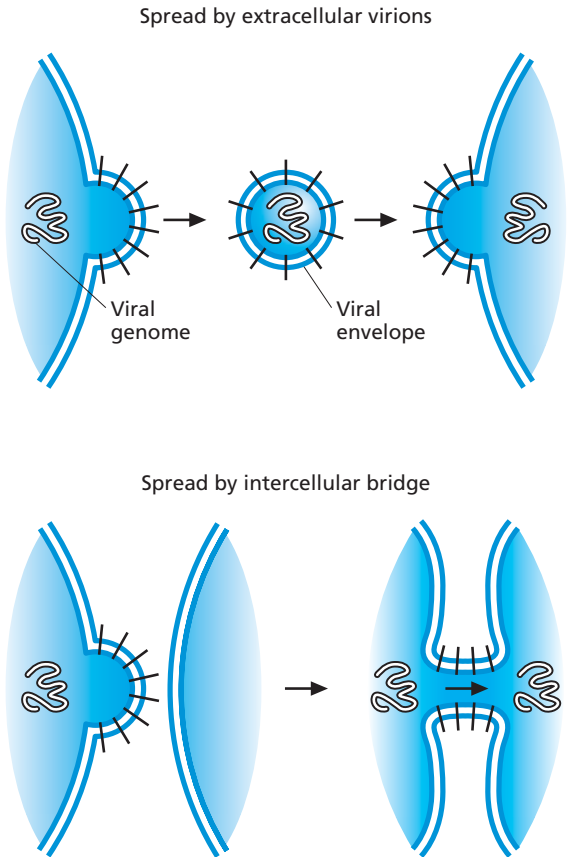

Figure 20 *Cell-to-cell transmission of a virus by intercellular bridges, a hypothetical reconstruction. Top, normal cell-to-cell spread of an enveloped virus as free extracellular virions. Bottom, cell-to-cell spread of the viral genome through a transient intercellular bridge. This phenomenon has been invoked to explain the spread of measles and rubella viruses during persistent infection of the brain.*

cules (Brodsky et al. 1999). Virus-infected target cells are rendered relatively less sensitive to virus-specific CTL attack, permitting them to continue to produce virions for an extended period of time.

Infectious immune complexes

In some instances where a virus persists in the presence of an active immune response, infectivity in the blood circulates in the form of immune complexes that are composed of infectious virions coated by virus-specific antibodies. Immune complexes can be demonstrated by the addition of anti-IgG antisera that will neutralize the infectivity. The molecular mechanism by which an antibody-coated virion can retain its infectivity has never been well elucidated. One possibility is that the complex is bound to Fc receptors on macrophages and internalized in vacuoles in which the complex dissociates, followed by infection of the macrophage. Consistent with this hypothesis, several of the persistent viruses (lymphocytic choriomeningitis virus, lactic dehydrogenase virus, and Aleutian disease virus) for which infectious complexes have been demonstrated, target macrophages as a major host cell.

Antigenic variation

During the course of persistent infection, there may be a selection for viral variants that are able to escape neutralization (Lutley et al. 1983). This phenomenon has been observed with several persistent lentiviruses such visna/maedi virus of sheep and equine infectious anemia virus. Equine infectious anemia virus (EIAV) is a lentivirus that produces a lifelong persistent infection of horses – the virus may be isolated from the blood even though the animals develop neutralizing antibody. Newly infected horses undergo discrete episodes of acute anemia, associated with bursts of viral replication. In each instance, the virus isolated during the episode of illness resists neutralization by serum obtained at the time of virus isolation (Table 12). However, the same serum can neutralize virus isolated at earlier times in infection. In other words, there is sequential replacement of virus with newly emerging variants that can escape neutralization. Ponies that survive repeated episodes of illness finally develop such a broad neutralization response that they can suppress all potential variants, thereby modulating, but not clearing, the smoldering infection. A similar evolution of virus during persistent infection has recently been shown to be a common phenomenon in persistent HIV-1 infections (Richman et al. 2003).

Escape mutants can also be selected by the cellular immune response (Aebischer and Mokophidis 1991; Allen et al. 2000; Ciurea et al. 2001). Most evidence for this phenomenon has been derived from experimental models (Schmitz et al. 1999; Evans et al. 1999; Allen et al. 2000), but it is possible that similar mechanisms play a role in naturally occurring persistent infections. Figure 21 shows an example where a macaque successfully immunized was able to contain a virulent challenge virus until a breakthrough occurred (Barouche et al. 2002). Analysis of viral isolates demonstrated that the breakthrough was associated with the emergence of a point mutation in the immunodominant epitope that was responsible for cellular immune control of infection.

Persistent viral infections often cause chronic diseases (McCune 2001). Some representative examples are set forth in Table 13.

HOST DETERMINANTS OF SUSCEPTIBILITY AND RESISTANCE

The outcome of the virus–host interaction is determined in part by host variables that can be conveniently considered under two categories, physiological factors and genetic determinants.

Table 12 *A smoldering infection associated with antigenic variation of the persistent virus*

Virus isolate (day of infection)	Fever spike (day of infection)	Neutralization index (log_{10}) of serum collected on the indicated day after infection					
		0 days	20 days	44 days	62 days	83 days	155 days
0 days		0	0	0.7	2.5	3.2	3.2
20 days	21	0	0	1.0	1.5	1.5	2.5
44 days	44	0	0	0	3.5	5.4	>5.4
62 days	62	0	0	0	0	2.0	2.0
83 days	83	0	0	0	0	0	3.5
155 days	155	0	0	0	0	0	0

Equine infectious anemia virus (EIAV) infection is associated with periodic febrile episodes. One infected horse experienced several fever spikes each lasting about 5 days, during which virus was isolated from the blood and was subsequently tested for neutralizability. Each virus isolate was neutralized by sera collected after the time of the isolate, but not by sera collected at or prior to the time of isolation. Likewise, each serum neutralized all the virus isolates made prior to the date of the serum, but none of the isolates made thereafter. This is evidence of continual antigenic drift of the virus, which probably explains the burst of replication associated with each fever spike, as well as the persistence of the virus in the face of an active neutralization response. After Kono et al. 1973.

Physiological factors

The host response to a viral infection may be influenced by a variety of physiological variables such as age, sex, stress, and pregnancy, all of which have been shown to influence the outcome of infection with some viruses (Brinton 1996). Age is perhaps the most consistently important variable in this category.

In general, very young animals are more susceptible than adult hosts to acute viral infections, and are more likely to undergo severe or fatal illness (Jubelt et al. 1980; Ogata et al. 1991; Tucker et al. 1993). However, it is important to recognize that in most mammalian species, young animals born of immune mothers receive maternal antibody either in utero by the transplacental route and/or postnatally, in colostrum and milk, or both. Furthermore, newborns have a special transport system that permits them to absorb intact immunoglobulin from the gut lumen into the circulation. The innate high susceptibility of infants born of non-immune mothers is revealed only in those rare instances where a virus has disappeared from an isolated community so that all age groups lack immune protection. A classical example is measles, which can be a devastating disease with a mortality of up to 25 percent in non-immune infants (Panum 1940; Morely 1969), but which is relatively benign in most societies where almost all women of childbearing age have acquired active immunity from natural infection or from measles vaccine. The mechanisms of enhanced susceptibility of newborn animals have been obscure, but recently it has been shown that an alphavirus induces apoptosis in neurons of newborn mice, but does not kill neurons from older mice in which enhanced expression of the cellular oncogene, bcl-2, blocks apoptosis (Levine et al. 1993).

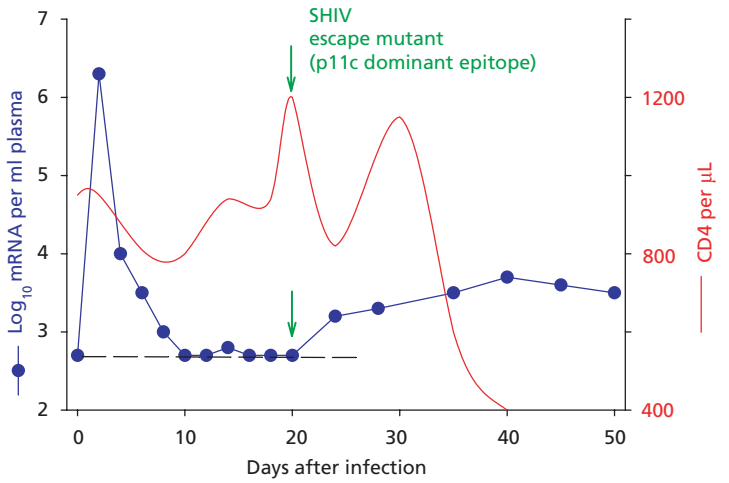

Figure 21 *Selection of viral variants that can escape the cellular immue response is one mechanism of viral persistence. In this example a monkey was immunized with a potent vaccine against SHIV (chimeric SIV–HIV virus) and then infected with a virulent SHIV strain. The monkey contained the infection quite effectively until the SHIV broke through due to emergence of a SHIV variant with a point mutation in an immunodominant epitope (data from Barouche et al. 2002).*

Table 13 *Diseases associated with persistent viral infections, selected examples*

Virus family/genus	Virus	Host	Disease
Oncogenic viruses			
Retroviridae	MuLV	Mice	Hematopoietic, lymphoreticular neoplasms
Hepadnaviridae	HBV	Humans	Hepatocellular carcinoma
Papillomaviridae	HPV	Humans	Cervical carcinoma
Herpesviridae	EBV	Humans	Burkitt's lymphoma
High titer persistence			
Arenaviridae	LCMV	Mice	Glomerulonephritis, vasculitis
Parvoviridae	Aleutian disease	Mink	Glomerulonephritis, vasculitis
Latent infections			
Herpesviridae	HSV	Humans	Cold sores, encephalitis
	CMV	Humans	Pneumonitis, retinitis, encephalitis
	EBV	Humans	Mononucleosis
	VZV	Humans	Herpes zoster
Smoldering infections			
Morbillivirus	Measles virus	Humans	Subacute sclerosing panencephalitis
	CDV	Dogs	Encephalitis, demyelination
Retrovirus	HTLV I	Humans	Tropical spastic paraparesis
Polyomavirus	JC	Humans	Progressive multifocal leukoencephalopathy
Lentivirus	VMV	Sheep	Interstitial pneumonitis, demyelination
	EIAV	Horses	Episodic hemolytic anemia
	HIV	Humans	AIDS

JC, the initials of the patient from whom virus was isolated; EIAV, equine infectious anemia virus; CDV, canine distemper virus; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HTLV-1, human T cell leukemia virus; LCMV, lymphocytic choriomeningitis virus; MuLV, murine leukemia virus; VMV, visna maedi virus; VZV, varicella zoster virus.

Less commonly, advanced age can also be associated with increased susceptibility to viral infection. St. Louis encephalitis is an example of this phenomenon (Table 14). In one epidemic, the ratio of encephalitis cases to infections was about 0.2 per 1 000 for children aged 0–9 years and about 3.0 per 1 000 for adults aged 60 and over. Another example is varicella zoster virus, which usually produces primary infections in childhood followed by latent infections of the spinal ganglia. Reactivations of latent infections, in the form of herpes zoster, rarely occur before age 50 (except in individuals with other debilitating illnesses), but are much more common over 60 years of age.

Table 14 *Age is one of the physiological variables that can determine host susceptibility*

Age group	Encephalitis rate per 100 000	Case-fatality rate per 100	Percent with SLE antibody
0–9	8	0	41%
10–19	13	0	29%
20–29	15	0	38%
30–39	14	0	36%
40–49	17	0	26%
50–59	28	13%	38%
60+	78	27%	25%

Age distribution of St. Louis encephalitis showing that attack rates increased strikingly in the older age groups, although the frequency of infection was similar for all ages.
Data from Luby et al., 1967; Henderson et al., 1970.

Host genes

Studies with inbred animals have documented that the outcome of infections often varies in different strains of mice (Brinton 1996), and genetic analyses have been conducted to determine the form of inheritance of susceptibility, and also to map the chromosomal location of the responsible genetic loci (Lodmell 1983; Oktsuka and Taguchi 1997). Several generalizations may be made, based on numerous studies of a wide variety of viruses:

- Most genetic loci control susceptibility to a specific family of viruses and not to all viruses.
- Susceptibility can often be mapped to a single autosomal locus, but multiple loci have been identified in some instances.
- When a single genetic locus has been identified, susceptibility may be either dominant or recessive.
- Where loci have been mapped, they are usually distant from the major histocompatibility locus, and in most such instances, the mechanism of susceptibility is not immunological.
- The exact mechanism of susceptibility has not been well defined in most instances, although there are some examples that map to the MHC, implying an

immunological explanation (Miyazawa et al. 1992; Poskophidis et al. 1994).

An example of genetically determined host susceptibility is shown in Table 15, in which there is a single autosomal genetic locus and resistance is dominant (Haller et al. 1980). In this instance, the genetic determinant, called the *Mx* locus, has been shown to influence the response to influenza viruses and is related to differential ability to mount an interferon response (Pavlovic et al. 1992; Staeheli et al. 1993). Thus, treatment with anti-interferon antibody abrogates resistance, and renders all strains of mice equally susceptible.

It is difficult to investigate genetic determinants of host susceptibility in an outbred population. Classical studies of myxoma virus in outbred rabbit populations (Fenner 1983) have clearly demonstrated genetic determinants that became manifest under the selective pressure of a virulent virus. Likewise, individual monkeys exhibit marked differences in susceptibility to Simian immunodeficiency virus (SIV) that correlates with ex vivo infectibility of their T lymphocytes (Goldstein et al. 2000). If it is assumed that there are human homologues for most mouse genes, then it may be inferred that the outcome of viral infections in humans is also influenced by genetic determinants. Consistent with this presumption are observations that human responses to standardized virus inocula may be somewhat variable (Table 10 and Figure 12).

Recent studies of HIV-1 have provided substantial evidence of a number of human genetic determinants of susceptibility to infection or to the rate of progression to overt AIDS (Liu et al. 1996; Kaslow et al. 1996; Migueles et al. 2000; Moore et al. 2002). The most striking of these is a polymorphism in the gene that encodes the chemokine receptor, CCR5, which is the major coreceptor for HIV-1. Some people have a deletion in the gene (Δ32 deletion) such that no CCR5 protein is expressed, and these individuals are at very low risk of HIV infection (Table 16). People who are heterozygous for the Δ32 deletion can be infected but, on average, have prolonged incubation periods to the onset of AIDS by comparison with $CCR5^{+}$ homozygous individuals.

Table 15 *Genetic determinants of host susceptibility can be delineated in inbred strains of mice*

Mouse strain	Genotype	Mortality dead/total	Log_{10} virus titer in blood
Not treated			
A/J	r/r	4/4	6.0
A2G	R/R	0/4	3.7
F1 (A/J × A2G)	R/r	0/4	3.5
Treated with anti-interferon antiserum			
A/J	r/r	4/4	6.0
A2G	R/R	4/4	6.3
F1 (A/J × A2G)	R/r	4/4	6.5

A/J mice are susceptible and A2G mice are resistant to a hepatotropic strain of influenza virus, and the F1 hybrid is also resistant, indicating that a single dominant autosomal gene determines resistance. In addition, treatment with anti-interferon antiserum abrogates resistance, suggesting that the effect is mediated through the action of interferon.
Data from Haller et al. (1980).
R, resistant; r, susceptible.

Table 16 *Differences in host susceptibility have been defined for a few viruses of humans*

HIV-1 antibody	Parameter	Total	CCR5 +/+	CCR5 +/−	CCR5 −/−
Positive	Number	1343	1148	195	0
	Percent	100%	85%	15%	0%
Negative	Number	612	508	87	17
	Percent	100%	83%	14%	3%

In this example, the chemokine receptor CCR5 acts as a coreceptor for most wildtype HIV isolates. A naturally occurring mutation (Δ32) in the CCR5 gene abrogates the expression of CCR5 and homozygous carriers of the mutation are resistant to HIV-1. Subjects at high risk of HIV exposure were divided into those who were HIV-infected and those who were not, and tested for their CCR5 status (CCR5 +/+, +/−, or −/−). There was a striking absence of $CCR5^{-/-}$ persons in the HIV-infected group and an excess of $CCR5^{-/-}$ persons (above the 1% expectancy) in the HIV-uninfected group.
After Dean et al. 1996.

Innate immune defenses	1	Examples of immune responses to specific viruses	11
T lymphocytes and immunity to viruses	5	Viral strategies for evading the immune response	17
The role of antibodies in immunity to viruses	7	Concluding remarks	19
Immunopathology in virus infection	9	References	19

Viruses and the immune system are continually involved in a sophisticated game of hide and seek. Whereas many virus infections are readily controlled by the immune response, some have evolved strategies to evade detection and persist in their host. This balance in the host–pathogen relationship is maintained by the immune system; a breakdown in immune surveillance can lead to recurrent infections and clinical disease.

The immune system employs a variety of strategies to combat virus infection. These can be divided into innate or 'nonspecific' defenses, which include interferon (IFN), natural killer (NK) cells, and macrophages, and adaptive or specific immunity that involves T cells and antibodies. The evolution of T-cell and antibody receptor diversity has probably been critical for the survival of higher vertebrates; it has enabled the host to match evolutionary mutations in structure used by viruses to evade host defenses (Janeway 1992; Zinkernagel 1995; Litman et al. 1999; Janeway and Medzhitov 2002).

Immunological defenses are marshaled at strategic areas in the body where entry of virus is favored. For example, IgA at mucosal surfaces functions by blocking virus adsorption and penetration, macrophages are located throughout the body in various tissues and IFN is produced by most cells in response to viral infection. Once the outer defenses are breached, viruses and viral antigens become channeled into the lymphoid system where they encounter T and B cells. A critical event in this process is the uptake and presentation of antigens by specialized antigen-presenting cells, which include dendritic cells (DC), macrophages, and B lymphocytes. From such encounters, antiviral T cells are generated that target and rapidly destroy infected cells, and antiviral antibodies are produced that protect the host from viremia and reinfection. How the immune response recognizes and kills virus-infected cells, how virus is neutralized by antibody and complement, and how these responses can have pathological outcomes will be discussed. These events will be contrasted with the evasion strategies employed by viruses.

INNATE IMMUNE DEFENSES

The innate defenses restrict early infection and limit spread to other tissues. Because this first line defense is mobilized within minutes or a few hours, it may hold the balance in the host response to virus infection. A key early surveillance mechanism against virus infection is mediated by Toll-like receptors (TLR) found on macrophages, DCs, and polymorphonuclear cells. TLR are a family of receptors with an extracellular domain containing leucine-rich repeats and an intracellular domain homologous to the cytoplasmic tail of the interleukin (IL)-1 receptor (Takeda et al. 2003). Signaling through TLR's leads to activation of NF-κB resulting in the production of pro-inflammatory cytokines. Of the current 11 TLR's, TLR-3 and TLR-7 are of interest here as they recognize dsRNA (TLR-3) and ssRNA (TLR-7) (Diebold et al. 2004). Restricting the early

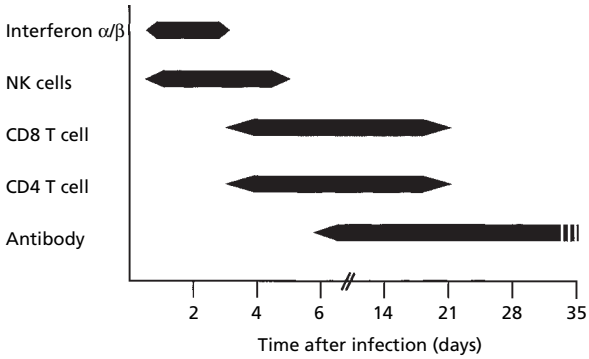

Figure 1 *Time scale of the innate and adaptive immune response.*

infection is the province of IFNs α and β, NK cells, and macrophages. The inflammatory response that follows this early encounter with viruses signals its location to the specific immune system, which becomes effective after a few days to a week. Only then will T cells home to the site of infection and antibody be active in limiting virus spread. A time scale for the evolution of the immune response is shown in Figure 1.

Antiviral properties of IFN

IFN is a first line of defense against viruses. There are two major families of IFN. Type I IFN, which includes IFN-α (leucocyte-type) encoded by 13 genes and IFN-β (fibroblast-type) encoded by a single gene on human chromosome 9 (mouse chromosome 4). Other type I IFN genes include human IFN-ω, IFN-τ/ϵ (trophoblast), and the recently described IFN-κ (LaFleur et al. 2001), and IFN-λ (IL-28/IL-29 family) (Kotenko et al. 2003). IFN-α/β is induced within hours of infection and initiates the antiviral state in neighboring cells via the IFN-α/β receptor. This results in the activation of a number of genes associated with the antiviral response as well as anti-proliferative and immunomodulatory activities. In contrast, type II IFN or IFN-γ is produced following antigenic or mitogenic activation of T cells and NK cells. IFN-γ binds to the type II IFN receptor and mediates a similar cascade of gene activation to type I IFN (for reviews see Vilcek and Sen 1996 and Goodbourn et al. 2000) (see also The role of cytokines in viral infections).

The antiviral response mediated by IFN involves three well described mechanisms, although several others probably exist. Of these protein kinase R (PKR) and 2′–5′ oligo adenylate synthetase are the best characterized. dsRNA-dependent PKR is activated by viral dsRNA and acquires a central role in initiating a number of interactions. PKR phosphorylates the α-subunit of eIF2 preventing the recycling of initiation factors resulting in a block in translation of viral RNA (Clemens and Elia 1997). PKR also mediates apoptosis via Bcl-2 and caspase-dependent mechanisms, thereby thwarting virus infection (Lee et al. 1997). In addition, PKR plays a role in signal transduction via NF-κB, important for activation of the *IFN-β* gene (Williams 1999). Although a key protein in a number of cellular events, PKR is not essential for IFN-mediated antiviral responses, as mice lacking PKR are still able to resist viral infection (Abraham et al. 1999).

2′–5′ oligoadenylate synthetase catalyses the synthesis of short oligomers (2′–5′ A oligomers) from ATP that act as potent activators of the latent endonuclease RNase L. This endonuclease mediates cleavage of ssRNA thereby inhibiting protein synthesis (Silverman 1999). This IFN mechanism is known to be effective against vaccinia virus and reovirus.

Mx proteins are found in all vertebrate species. They are readily induced by type I IFN and function by inhibiting transcription of a range of RNA viruses including orthomyxoviruses and paramyxoviruses.

Other IFN-dependent mechanisms clearly exist, since mice deficient in PKR, RNase L, and Mx (triple gene knock-out) still retain antiviral activity (Zhou et al. 1999). Other likely mechanisms include dsRNA-dependent adenosine deaminase (ADAR) and caspases 1, 3, and 8.

IFNs play a major role in the immunomodulation of innate and adaptive immune responses. IFN-α/β is an important activator of major histocompatibility complex (MHC) class I and NK cell activity. IFN-γ is a powerful inducer of MHC class I and class II expression, as well as the machinery involved in antigen presentation, for example, proteosomes and TAP-1 and TAP-2 peptide transporters. This augments the activity of cytotoxic T cells (CTL) making them more efficient killers of virus infected cells (see section entitled T lymphocytes and immunity to viruses). Other roles for IFN-γ include directing $CD4^+$ T cells towards a Th1 phenotype, and activating the antiviral state of macrophages.

The importance of type I IFNs in antiviral immunity stems from three experimental approaches: (1) the local administration of IFN to sites such as the nasal passage which protects against rhinovirus infection (Merigan et al. 1973); (2) the administration of anti-IFN antibodies to neutralize IFN-α/β in mice which leads to an increased susceptibility to infection with vesicular stomatitis virus (VSV) and herpes simplex virus (HSV) (Gresser et al. 1976); and (3) the use of IFN receptor gene knock-out mice. The last demonstrates, quite dramatically, the importance of IFN in arresting viral replication in vivo. A variety of RNA viruses (lymphocytic choriomeningitis virus (LCMV), VSV, Theiler's murine encephalomyelitis virus), and DNA viruses (vaccinia, herpesviruses) show increased replication and pathogenic effects in IFN-α/β receptor knock-out mice (van den Broek et al. 1995).

NK cells in antiviral immunity

NK cells are large granular lymphocytes distinct from T- and B-cell lineages. Human NK cells are characterized

by the presence of CD16 and CD56 markers. Mouse NK cells have NK1 or NK2 and asialo-GM1 markers that are used to study their function in vivo. A population of NK1.1, $CD8^+$ cells has been described, which have important regulatory functions in the immune response (Vicari and Zlotnik 1996). NK cells produce a number of cytokines involved in antiviral immunity (see The role of cytokines in viral infections), including IFN-γ, tumor necrosis factor α (TNF-α), tumor growth factor β1 (TGF-β1), granulocyte–macrophage colony-stimulating factor (GM-CSF), and IL-1β (Trinchieri 1989; Perussia 1991).

NK cells display a number of receptors involved in the activation and inhibition of NK cell function. Activation receptors include NKp30, NKp44, and NKp46 on human NK cells and Ly49D and Ly49H on mouse NK cells. These receptors are involved in recognition of virus infected cells with NKp46 recognizing influenza hemagglutinin and Ly49H recognizing m157 of murine cytomegalovirus (Mandelboim et al. 2001; Arase et al. 2002). Other activation receptors include LFA-1 and CD2 members. In addition, NK cells have receptors for a number of cytokines known to be important in activation and proliferation, for example, type I IFN, IL-2, IL-12, IL-15, and IL-18.

In order to protect normal cells from overt NK cell activation and damage, NK cells also carry a variety of inhibitory receptors. This includes the killer cell immunoglobulin-like receptors (KIR), immunoglobulin-like inhibitory receptors (ILT), and lectin-like heterodimers CD94–NKG2A. These receptors bind most MHC class I molecules and deliver inhibitory signals to the cells via immunoreceptor tyrosine-based inhibitory motifs (ITIM). This ability to regulate NK-cell activation has been exploited by some viruses by mimicking inhibitory receptors thereby confusing NK cells at sites of infection (see section Interference with MHC function and NK cell recognition, below).

NK cells can also recognize IgG antibody-coated cell surfaces via FcγRIII (CD16) and kill target cells. This process, known as antibody-dependent cell cytotoxicity (ADCC), is a highly efficient mechanism for activating NK cells and precipitating rapid destruction of virus-infected cells. Cell killing is mediated by a perforin-dependent mechanism (Kagi and Lederman 1994).

NK cells seem to be rapidly mobilized following virus infection. They are detected at sites of infection within 2 days of virus entry, and their appearance is related to a rise in type I IFN levels in the blood. Initial encounter of NK cells with virus-infected cells results in a 'bystander' proliferation mediated by cytokines such as IL-15 and type I IFN. The latter is known to induce blastogenesis in NK cells, probably via up-regulation of IL-15 (Nguyen et al. 2002). After the initial phase of nonspecific activation, there appears to be a more selective amplification of NK cells. In murine cytomegalovirus infection there is a preferential selection for Ly49H-expressing NK cells that appear around day 4–6 following recognition of m157 encoded by the virus (Dokun et al. 2001; Arase et al. 2002). This specific expansion of NK cells is only seen during murine cytomegalovirus (MCMV) infection in resistant mouse strains. Conversely, m157 also interacts with Ly49I, an inhibitory molecule on NK cells. This interaction predominates in MCMV-susceptible mouse strains which lack Ly49H. Around day 6 of MCMV infection there follows a contraction of NK-cell expansion at a time when there is a rise in the adaptive immune response.

Mice vary in susceptibility to MCMV. Resistance to infection is controlled by both *H-2* and non-*H-2* genes. The latter was identified as a single autosomal dominant gene called *Cmv-1* (Scalzo et al. 1992). This gene is located on chromosome 6 and is linked to the NK cell complex, which includes *NK1.1* and *Ly49* genes. Depletion of NK cells in mice bearing the *Cmv-1* gene increases viral replication, proving the link between this gene and NK cell activity (Scalzo et al. 1990). The *Cmv-1* gene has now been identified as Ly49H which targets the m157 protein on MCMV infected cells.

An interesting series of experiments involves the role of NK cells in immunity to vaccinia. Athymic nude mice are highly susceptible to vaccinia but are resistant to vaccinia virus expressing the *IL-2* gene. The mechanism of resistance in this instance involves activation of NK cells by IL-2 to produce IFN-γ, which mediates protection, probably via macrophage activation (Karupiah et al. 1990).

In humans, NK cells are considered to play an important role in immunity to herpesvirus infections. A single NK cell-deficient patient has been reported with severe herpesvirus infections, including cytomegalovirus (CMV) and varicella-zoster virus (VZV) (Biron et al. 1989, 1999).

The key role of macrophages and DCs in immunity to viruses

Macrophages are strategically located throughout the body as a first line of defense against infectious agents. Their importance in virus infections is often underestimated; nevertheless, they have potent antiviral activity and serve to limit virus spread. Macrophage antiviral activity can be broadly divided into intracellular and extracellular defense mechanisms. Macrophages are major producers of IFN-α found in the blood stream following infection. Other antiviral molecules produced by macrophages include:

- TNF-α, which functions either by inducing genes coding for 2′–5′A synthetase and Mx, or by selectively killing virus-infected cells, via apoptosis (Wong and Goeddel 1986).
- Arginase, which depletes local arginine concentrations and effectively aborts HSV infection (Bonina et al. 1984; Mistry et al. 2001).

- Nitric oxide synthase, which is induced following IFN-γ activation of macrophages and leads to the generation of nitric oxide which inhibits the replication of vaccinia virus and HSV (Karupiah et al. 1993).

For many viruses, the hostile environment of a phagolysosome leads to a loss of infectivity. Here, both oxygen-dependent and oxygen-independent mechanisms are likely to contribute to the inactivation of certain viruses. Viruses can be targeted for intracellular destruction by phagocytosis of infected cells or by opsonization of virus–antibody complexes via the Fc receptor; the latter is an efficient way of removing virus from the blood stream. Macrophages can also kill virus-infected cells either by direct contact or, more efficiently, by ADCC through recognition of IgG antibody. In herpesvirus infections, neutrophils have also been implicated in the destruction of infected cells via ADCC.

Despite the hostile nature of macrophages, some viruses selectively exploit these cells for growth and survival; they include lactate dehydrogenase virus, maedi-visna virus, human immunodeficiency virus (HIV), and CMV.

DCs play a major role in the induction of the adaptive immune response (see section entitled T lymphocytes and immunity to viruses). However, it is now apparent that multiple subsets of DCs exist, some of which may have specialized functions in the control of virus infection (Shortman and Liu 2002). An example is the plasmacytoid-derived DC-2 which is a major producer of type I IFN (Siegal et al. 1999). They have been found during influenza virus, HSV, and CMV infections where they appear at sites of infection and in lymphoid tissue associated with infection. During influenza virus infection, DC-2 cells make large amounts of IFN-α which results from endosomal recognition of viral RNA by TLR-7 and activation through MyD88 (Diebold et al. 2004). One role for DC-2 cells is to orchestrate the innate immune response through production of IFN-α. This almost certainly involves activation of NK cells and NKT cells. NK cell–DC interactions are known to be important in the response to MCMV infection (Andrews et al. 2003). This interaction is independent of DC-2 cells and favors a subset of DCs in the mouse that are $CD8^+$.

Collectins and the complement system

Collectins are soluble proteins found in serum, lung, and nasal secretions that can act as a first line of defense against infectious agents (Epstein et al. 1996). They include mannose-binding lectin (MBL) (also known as mannose-binding protein), conglutinin, and lung surfactant proteins A and D (SP-A, SP-D). The basic structural unit is composed of a collagen stalk and a globular head with a lectin-binding domain. Each unit exists as a trimer or multimeric complex. These structural features are similar to the first complement protein C1q. The collectins constitute a primitive antibody-like defense able to target diverse carbohydrate structures on pathogens and yet distinguish self from nonself structures. MBL interacts with HIV, influenza virus, and hepatitis B virus (HBV), and is capable of activating the classical complement pathway to neutralize the virus (Malhotra and Sim 1995; Reading et al. 1997; Hakozaki et al. 2002).

Complement proteins can also directly target viruses or virus-infected cells. Human serum is particularly efficient in the neutralization of certain retroviruses (e.g. murine leukemia virus (MLV)). Human C1q binds the p15E protein of MLV, resulting in activation of the complement system and neutralization of the virus by a process termed virolysis, i.e. damage to the virion envelope (Bartholomew et al. 1978). Classical complement pathway is also activated by CMV-infected cells (Spiller and Morgan 1998) and by cell-free humanT-lymphotropic virus type 1 (HTLV-1) (Ikeda et al. 1998). Sindbis virus is also able to activate the classical complement pathway, but can also directly activate the alternative pathway, i.e. via C3. Other important roles for complement involve interaction with antibody: these events are discussed in the section entitled The role of antibodies in immunity to viruses. C3a and C5a are both inflammatory mediators and as such can serve as signals for alerting inflammatory cells to sites of infection. This is probably one of the reasons why some viruses e.g. herpesviruses and poxviruses carry genes able to subvert C3 activation (see section entitled Viral strategies for evading the immune response). A summary of the complement activation pathways and their functions is shown in Figure 2.

The significance of the complement system in antiviral immunity has been difficult to evaluate. In humans and animals, natural deficiencies of complement components do not predispose the host to severe virus infection (Lachmann and Rosen 1979). Experimental approaches have involved the administration of cobra venom factor to exhaust endogenous C3 and hence incapacitate the complement system and the use of complement deficient, i.e. gene knock-out mice. Although most virus infections studied were not affected by depletion of C3, with Sindbis virus an increased viremia was observed in the depleted mice (Hirsch et al. 1980).

Summary of innate immunity

Innate immunity performs an essential role in the early stages of virus infection. Components of the system act rapidly and initiate the cascade of events that focus the specific immune response on the infected area. Factors released in the processes described above lead to an up-regulation of adhesion and MHC molecules on local blood vessels, which enable lymphocytes to extravasate and enter the parenchyma. Chemoattractants produced

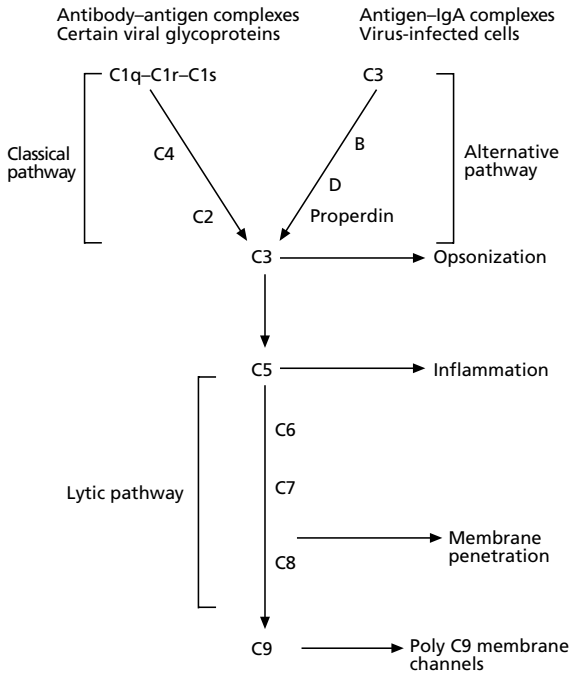

Figure 2 *Activation of the complement cascade by virus infection.*

by mast cells, macrophages, NK cells, and complement components recruit lymphocytes, which can then interact with antigen-presenting cells both at the site of infection and in the local lymph nodes.

T LYMPHOCYTES AND IMMUNITY TO VIRUSES

T lymphocytes are central for inducing immunological responses and, in many instances, for the recognition and destruction of virus-infected cells. A deficiency or complete absence of T cells in a host often predisposes to severe or fatal disease. This is particularly so in patients who are severely immunocompromised during organ transplantation. These individuals are at particular risk from reactivating herpesviruses, such as CMV and Epstein–Barr virus (EBV). The complex interrelationship between HIV and humans is another example of an apparent selective immunodeficiency of $CD4^+$ T cells leading inexorably to opportunistic infection in which CMV becomes a life-threatening infection.

Our understanding of the importance of T cells in viral infections stems from studies in animal models. In mice, selective immunodeficiency states can be 'manufactured' using gene knock-out technology (Doherty 1993a). These enable specific questions to be addressed on the function of different T-cell populations and their products (for example, cytokines and receptors). A similar approach involves the use of monoclonal antibodies to interfere selectively with the function of lymphocytes and other cells and cytokines. The advantage of these techniques is that cell activity can be interrupted before or during an infection, thus permitting examination of the induction and effector capacity of the immune response. The inbred nature of laboratory mice also enables specific T-cell populations and clones to be adoptively transferred to syngeneic recipients and their function monitored. This approach has implications for immunotherapy in humans, in whom protection of high risk transplant patients from CMV disease can be achieved by the transfer of selective anti-CMV T-cell clones derived from the patient prior to immunosuppression (Riddell and Greenberg 1994).

These powerful techniques emphasize the importance of α/β T-cell receptor populations, in particular the role of $CD8^+$ T cells in immunity and immunopathology of virus infections. The significance of γ/δ T cells in antiviral immunity is still unclear although they are found at sites of virus infection, suggesting a role in defense (Born et al. 1991). They have a more restricted receptor repertoire than α/β T cells and are thought to recognize different restriction elements, including CD1 molecules (Sciammas et al. 1994). In this section we focus on the activities of α/β T cells.

Central role for $CD4^+$ T cells in the induction of the immune response to viruses

As with any antigenic challenge, the initial events in the induction of immunity involve the uptake of virus or viral proteins by DCs and processing to peptides for presentation by MHC class II molecules (Watts and Powis 1999). Briefly, antigen is internalized in endosomes and subjected to proteolytic degradation. These endosomal compartments then fuse with vesicles carrying MHC class II molecules to the cell membrane. MHC class II arises in the endoplasmic reticulum (ER) complexed with the invariant chain. The invariant chain serves two important functions: (1) to target MHC class II to the trans-Golgi and (2) to block the MHC class II cleft from binding peptides prematurely in the ER. On fusing with endosomes, a combination of the acidic pH and MHC class II M molecules (a nonclassic MHC class II molecule) dissociates the invariant chain and allows peptides of around 15 amino acids in length to associate with MHC molecules (Busch and Mellins 1996). Recognition of this structure on the antigen-presenting cell is by the T-cell receptor (TCR) and CD4 molecule on T cells. Additional secondary interactions between cell surface receptors, for example B7 and CD28, LFA-1 and ICAM 1/2, LFA-3, and CD2, lead to signal transduction and the production of IL-2 and IL-2 receptors, resulting in clonal expansion of the interacting $CD4^+$ T cell (Dustin and Springer 1991; Montoya et al. 2002). These events initiate the T helper cell response, which catalyses the induction of $CD8^+$ CTLs, activates NK cells and macrophages, and is critical for induction of the

T-dependent antibody response. Many of these amplifying events involve cytokines and the interaction with key cell surface molecules CD40 and CD40L (T-cell ligand) and B7.1 and CD28. B lymphocytes are the other major antigen-presenting cells in the immune system and are particularly effective at presenting to memory T cells. Figure 3 outlines the various helper interactions mediated by CD4 T cells.

Recognition of virus-infected cells by $CD8^+$ T lymphocytes

$CD8^+$ T cells recognize a complex of MHC class I with a foreign (virus) peptide on infected cells. The process by which viral antigens are processed and presented is referred to as the endogenous antigen-presenting pathway (Lehner and Cresswell 1996). Briefly, newly synthesized viral proteins are degraded in part by a complex of proteolytic enzymes called the proteosome. Small peptides generated by this process are actively transported via peptide transporters (TAP1 and 2) to the ER where they associate with the MHC class I heavy chain. Peptides may be trimmed by enzymes in order to fit snugly into the MHC cleft which accommodates peptides of around nine amino acids. The light chain (β2-microglobulin) associates with the heavy chain and the trimolecular complex is transported to the cell surface. The evolutionary advantage of this process is that peptides derived from intracellular pathogens can be processed at an early stage in the infection, well before replication or assembly of new virions has occurred. If they can be recognized by the immune system the infectious agent can be rapidly eliminated. The fact that viral immediate early and early antigens can be recognized by T cells supports this view.

Selection for the relevant peptides can occur at three stages in this processing pathway: (1) the proteosome, i.e. where peptide cleavage occurs according to the enzymatic specificity within the proteosome; (2) the peptide transporters that show a preference for selecting certain C-terminal amino acids; and (3) the MHC molecule for which many allelic forms exist, all differing at the peptide-binding groove/cleft.

Because MHC class I molecules occur on virtually all nucleated cells, viruses will have difficulty avoiding the attentions of cytotoxic CD8 T cells. They have, however, evolved some intriguing strategies to disrupt antigen presentation, discussed below (see section entitled Viral strategies for evading the immune response). One strategy adopted by HIV involves antigenic variation and T-cell receptor antagonism. Mutation in antigenic peptides is a feature of HIV infection. Changes can occur that affect (1) peptide binding to MHC class I molecules, (2) peptide recognition by the TCR, and (3) peptide processing by proteosomes. In (3), alterations to amino acids flanking either side of an antigenic peptide could alter peptide processing. Altered peptides affecting TCR recognition can antagonize the T-cell response to the unmutated antigenic peptides (Klenerman et al. 1996).

T cells in antiviral immunity

The importance of particular T-cell subsets in immunity to viruses depends on several, often interrelated, factors, including the nature of the infecting virus, dose of infecting agent, route of infection, and age of the host.

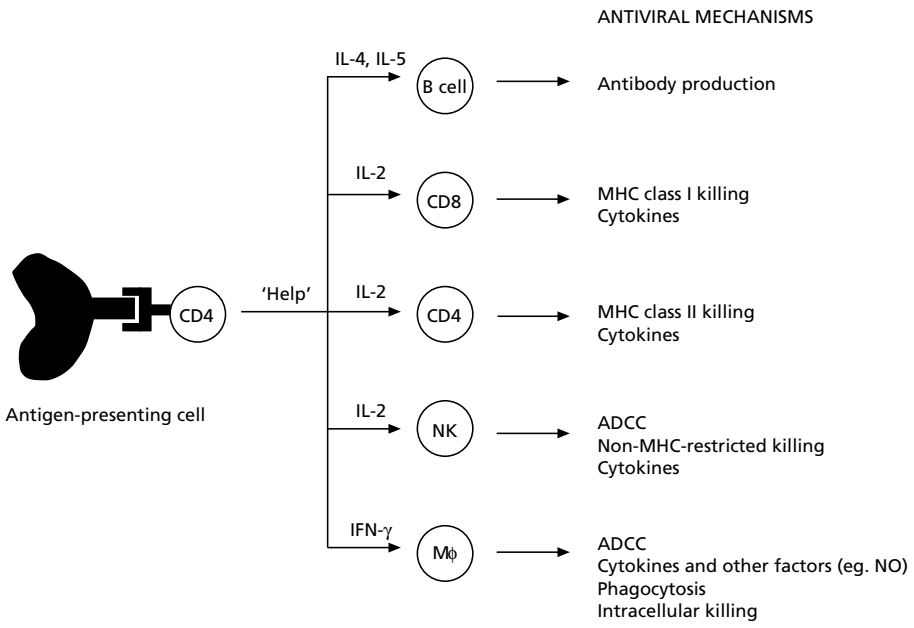

Figure 3 *CD4 T cell 'help' for other arms of the immune response. ADCC, antibody-dependent cell cytotoxicity; IL, interleukin; MHC, major histocompatibility complex; Mϕ, macrophage.*

Since 1976, a vast amount of information has been generated on the role of T cells in a number of virus infections, including the well-studied examples of influenza virus, LCMV, vaccinia virus, HSV, and HBV. A more detailed analysis of the immune response to selected virus families is provided in the section entitled Examples of immune responses to specific viruses. These studies indicate a direct role for CD4 and CD8 T cells in recovery from infection, which is emphasized in studies on mice deficient in MHC class I and II genes.

Targeted disruption of β2-microglobulin resulted in low levels of MHC class I expression. These mice have normal CD4 T cells but are severely lacking in CD8 T cells. Such deficient mice infected with LCMV had an impaired ability to clear the infection, stressing the importance of CD8 T cells in this process. In contrast, when these mice were infected with influenza, Sendai or vaccinia viruses they cleared the infection normally. This was surprising, because previous experiments on the adoptive transfer of CD4 or CD8 T cells from infected mice had indicated that CD8 T cells were central to recovery and that CD4 T cells contributed to pathology of the lung infection (Leung and Ada 1982). Not all antiviral CD4 T-cell responses are pathological in outcome, many play an important role in recovery from infection through interaction with B cells and in activating cell-mediated immune responses. In cutaneous HSV infection of mice, a clear role for CD4 T cells exists in clearing virus from the epidermis. The mechanism of protection involves IFN-γ and macrophage recruitment and activation, and resembles a delayed hypersensitivity response (Nash and Cambouropoulos 1993). Similarly, control of vaccinia virus infection of ovaries and VSV infection of the central nervous system (CNS) is mediated by an infiltrating CD4 Th1 response, but not by a CD4 Th2 response (Maloy et al. 2000).

Mice deficient in MHC class II molecules had a deficient CD4 response but normal numbers of CD8 T cells. Infection of these animals with influenza virus resulted in the generation of a virus-specific CD8 T-cell response and recovery from infection (Bodmer et al. 1993). This and previous observations on HSV infection in CD4 T-cell-deficient mice (Nash et al. 1987) indicate that virus-specific CD8 T cells can be induced in a 'helperless' environment. It is interesting that, in mice with a CD4 disrupted gene, there is a failure to maintain a LCMV-specific CD8 T-cell response, leading to persistence of the virus (Battegay et al. 1994). These data argue in favor of a role for CD4 T cells in the maintenance of a continuing CD8 T-cell response and of T-cell memory. In fact, the number of memory T cells arising from an infection is related to the extent of the CD8 T-cell expansion during the primary response (Marshall et al. 2001). The maintenance of T-cell memory is related to the presence of cytokines such as IL-7 and IL-15 (Becker et al. 2002; Tan et al. 2002) and not the continued presence of antigen (Murali-Krishna et al. 1999).

How do CD4 and CD8 T cells mediate antiviral immunity in vivo? Following recognition of the relevant restriction element (MHC class I or II molecules) and T-cell activation, the effector activity of T cells involves cytolysis of the infected cell or control of infection by cytokines, or both. Cytolysis can occur via perforin and the fragmentins, e.g. granzymes, Fas–Fas ligand interaction and tumor necrosis factor (TNF) (Doherty 1993b). The key cells in cytolysis are the CD8 T cells; 'killer' CD4 T cells have been described in measles and HSV infections but are clearly limited to target cells expressing MHC class II molecules (Yasukawa and Zarling 1984). The major cytokines in antiviral immunity include IL-2, IFN-γ, and TNF.

The importance of cytolytic mechanisms in vivo has been demonstrated by targeted gene disruption. Mice deficient in perforin expression are susceptible to LCMV infection. Susceptibility is correlated with a considerably reduced ability of CD8 T cells to lyse infected target cells in vivo. However, some lytic activity is still detected which is attributed to Fas-mediated cell death (Kagi and Lederman 1994). In murine gammaherpesvirus infection, perforin does not seem to be essential for antiviral immunity mediated by CD8 T cells (Usherwood et al. 1997).

In many virus infections the destruction of certain tissue cells by cytolytic mechanisms may be an unacceptable price for the host to pay. Consequently, nondestructive mechanisms that eliminate the virus but spare the cell are biologically advantageous. Cytokines clearly fulfill this role and are now viewed in a much more positive light as effector molecules in viral infections (Ramshaw et al. 1992; Ramsey et al. 1993) (see also The role of cytokines in viral infections). Perhaps the best characterized is IFN-γ. A striking illustration of cytokine-mediated antiviral immunity is seen in HBV transgenic mice where clearance of virus is mediated in the absence of cell death, thereby 'curing' the infected cell (Guidotti et al. 1999) (see also section entitled Immune response to hepatitis B, below).

THE ROLE OF ANTIBODIES IN IMMUNITY TO VIRUSES

In general, antibodies appear 5–7 days after virus infection. The first antibody class to appear is IgM, which is usually of low affinity. Such antibodies are effective in controlling the spread of virus in the blood stream. As the antibody response evolves and affinity maturation proceeds (a process involving B cell proliferation leading to somatic mutation of immunoglobulin V regions and immunoglobulin class switching) IgG becomes the dominant class in serum and is characterized by increased affinity for viral antigens (Wabl and Steinberg 1996). Such antibodies are the major defense against reinfection by virus, which becomes neutralized by a variety of mechanisms (see section entitled Destruction of infected cells,

below). The main antibody defense at mucosal surfaces involves IgA, which occurs as a dimeric immunoglobulin with a secretory piece which protects them against the hostile environment of the gut and other mucosal sites. As discussed in the section entitled Destruction of infected cells below, antibodies form an important link with the innate immune response where they focus and activate the complement system and interact with a variety of phagocytic cells and lymphocytes via receptors for the Fc region of IgG (FcγR) and complement (CR). This combined response leads to neutralization of virus or lysis of virus-infected cells or phagocytosis.

Mechanisms of antibody-mediated neutralization of virus

The process whereby antibody neutralizes a virus is extremely varied and depends on the nature of the viral epitope, the class of antibody, and the nature of the infected cell (for review, see Dimmock 1995 and Klasse and Sattentau 2002). This process falls into two parts: neutralization at the cell surface and neutralization within the cell. A summary of the various antiviral mechanisms involving antibody is shown in Figure 4.

An obvious mechanism involves the blockade of virus ligand–cell receptor interaction. However, this event is quite rare, because a build-up of antibody on the virion surface is necessary in order to occupy all the available attachment sites, thus making the process inefficient from the viewpoint of the host defenses. Steric hindrance of receptor–anti-receptor interaction occurs with antibody neutralization of rhinoviruses. Here the antibodies attach to the rim of a 'canyon' or pit on the virion which is the site for binding to ICAM-1 on the cell membrane (Rossman 1989). In the early stages of the immune response, when antibodies have a low affinity for viral antigens, activation of the complement system can augment neutralization. This is illustrated with monoclonal antibodies that neutralize only in the presence of complement. The rapid build-up of complement on the virion membrane can lead to steric hindrance of virus–cell interaction or lysis of the virion envelope.

Another form of antibody-mediated neutralization involves inhibition of penetration of the virion. This might involve interfering with the fusion of the virion envelope with the cell membrane, as seen with HIV (Dimmock 1995). This process is probably the main mechanism of neutralization of paramyxoviruses and herpesviruses.

Even when a virus has entered the cell it is still subject to neutralization by antibody. For example, fusion with the endosome is a key mechanism used by influenza virus to enter the cytoplasm. To achieve this, hemagglutinin undergoes a major conformational rearrangement to engage and fuse with the endosomal membrane. Antibodies have been implicated in inhibiting this process (Wharton et al. 1995). Certain nonenveloped viruses enter the cell by adsorptive endocytosis, and changes in local pH lead to acidification and eventual uncoating. Poliovirus undergoes a series of changes resulting in a reduced sedimentation coefficient from 160S to 140S to 80S. Several neutralizing antibodies have been defined that inhibit this progression, blocking uncoating (Vrijsen et al. 1993). A similar process occurs with adenovirus, in which the anti-hexon antibody inhibits the pH-dependent changes required for fusion with the endosome and infectivity (Wohlfart 1988). In rare instances, antibody can neutralize infectivity after uncoating has taken place. With influenza virus, transcription is blocked by a failure of the ribonucleoprotein to function (Armstrong and Dimmock 1992).

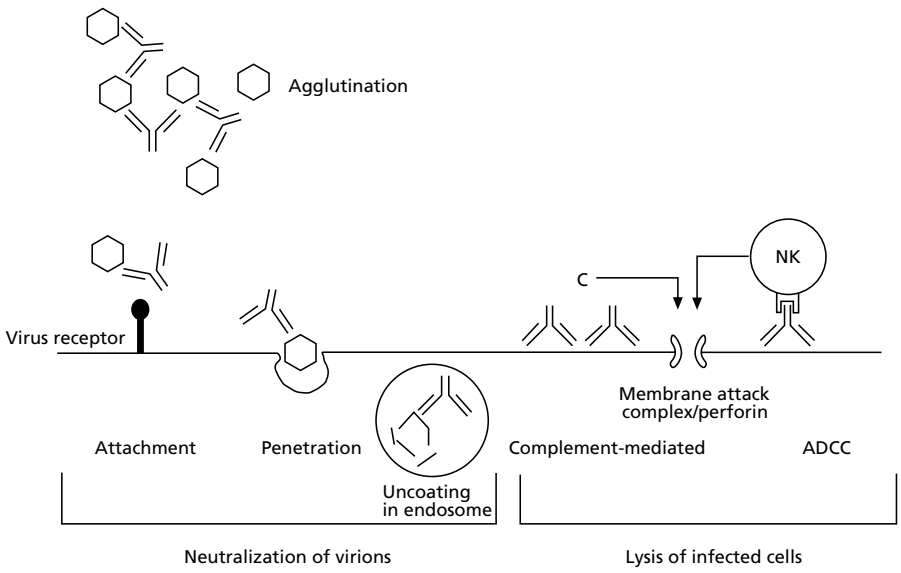

Figure 4 *Antiviral effector mechanisms mediated by antibodies. ADCC, antibody-dependent cell cytotoxicity; C, complement; NK, natural killer.*

Other direct effects of antibody

In neurons infected with Sindbis virus, replication is inhibited following antibody binding to viral glycoproteins on the cell membrane. This occurs with neutralizing and nonneutralizing monoclonal antibodies and is independent of complement and ADCC. The mechanism is unclear but may involve up-regulation of some cytoplasmic defense system (Levine et al. 1991; Levine and Griffin 1992).

Neutralization by IgA is a highly effective method of inhibiting virus invasion at mucosal surfaces. This can take place at two levels: extracellular and intracellular neutralization of virus. The latter is thought to occur in polarized cells in which IgA passes through via the poly-Ig receptor from the luminal to the apical surface. It is speculated that, during this process, vesicles containing IgA interact with those containing virus, leading to neutralization (Mazanec et al. 1992, 1993).

Antibodies can inhibit the release of some viruses from the infected cell. Examples include the herpesviruses in which antibodies to glycoprotein H of HSV-1 can block virus egress. Antibodies are also effective in blocking virus-induced cell fusion, thereby inhibiting syncytial (giant cell) formation.

Destruction of infected cells

Antibody can contribute to the destruction of virus-infected cells in two ways: complement-dependent lysis and ADCC.

Usually, a high density of membrane-bound antibody (calculated to be of the order of 5×10^6 IgG molecules/cell) is required for complement-mediated lysis of measles virus-infected cells. Clearly, such mechanisms are likely to be effective late in the infectious cycle. It is interesting that in most cases of antibody-targeted complement-mediated lysis it is the alternative complement pathway that becomes activated and not the classical pathway as one might have predicted (Sissons 1984).

ADCC is a highly efficient process, requiring only small quantities of bound IgG (10^3 molecules/cell). With HSV-1-infected cells ADCC is effective early on, before new progeny virus is assembled and released (Kohl 1991). The types of cell involved in this process have been discussed in the sections entitled Antiviral properties of IFN and NK cells in antiviral immunity, above.

Significance of antiviral antibody mechanisms in vivo

It is likely that all the antibody mechanisms discussed above contribute to immunity in the host. Studies with monoclonal antibodies have allowed dissection of the role of specific mechanisms. Antibodies that neutralize viruses in vitro are also effective at inhibiting their replication in vivo. This is illustrated by the inactivation of respiratory syncytial virus (RSV) by Fab fragments directed against the F protein of the virus (Crowe et al. 1994). This observation has formed the basis for the therapeutic use of 'humanized' anti-F protein antibodies in the treatment of RSV infections.

Nonneutralizing monoclonals against some viruses (e.g. HSV-1) can also protect against infection when passively administered to mice. The antibodies function in the absence of an active complement system (i.e. in C5-deficient mice), indicating a likely role for ADCC (Kohl 1991).

Passive delivery of antibody is an important natural process in the protection of the newborn. Transplacental transport of IgG antibodies offers an important initial defense against microbial invasion, allowing the infant's immune system time to develop. Likewise, antibodies delivered via colostrum are a major defense against rotavirus infections.

Despite the obvious advantages of antiviral antibodies in preventing infection, individuals with natural deficiencies in antibody are generally not prone to severe virus infections. Exceptions include echovirus infections, in which individuals with X-linked agammaglobulinemia (XLA) are prone to chronic infections of the CNS and muscles that can prove fatal (McKinney et al. 1987).

Summary of T- and B-cell immunity

T and B lymphocytes form an integrated system that tailors the immune response specifically to the relevant virus infection. In addition to specificity, the system retains a memory of the viruses to which it has been exposed, so that the host can be protected better on subsequent encounter. Central to the specific response is the CD4 T cell, which produces growth factors that induce the proliferation and differentiation of both T and B lymphocytes to magnify an immune response. In addition, 'help' from CD4 T cells enables B cells to produce higher affinity antibodies as the response progresses, which are more potent in binding to virus proteins. Such antiviral antibodies can neutralize free virions, and are therefore effective in infections in which there is a cell-free viremia. CTLs then complement antibody by destroying cells that have already been infected. In influenza virus infection, CTLs are necessary to resolve an initial infection; however, antiviral antibody prevents virus spreading in the body and provides subsequent protection from reinfection with the same virus strain.

IMMUNOPATHOLOGY IN VIRUS INFECTION

In any virus infection there is a likelihood of pathological damage to tissues by the immune system. The mechanisms associated with damage are varied and depend on

the nature of the virus, its tissue tropism, and the antigenic load associated with the infection. Examples of virus-induced immunopathology are listed in Table 1.

Antibody-mediated pathology

Antibody-mediated damage can be divided into immune complex diseases and enhancement of virus infectivity. Antibody-dependent enhancement (ADE) of virus infection is a process whereby virus-specific antibodies enhance the entry of virus into macrophages via interaction with Fc and/or complement receptors (Porterfield 1986; Tirado and Yoon 2003). The phenomenon is observed with many diverse virus infections, for example, flaviviruses to poxviruses, with the common theme that they target macrophages as a site of infection, that they preferentially induce a weak neutralizing antibody response in the infected host, and that they are associated with persistent, viremic infections. ADE has been implicated in a number of human and animal viral diseases. The most compelling examples include dengue virus, Aleutian mink disease virus (AMDV), and feline infectious peritonitis virus (FIPV) (Weiss and Scott 1981; Halstead 1982). In dengue virus infection, children aged <1 year are particularly susceptible, probably because of waning protective maternal antibody leading to infectious immune complexes resulting in exacerbation of infection. This enhancement of infectivity can lead to dengue hemorrhagic fever or dengue shock syndrome (Halstead 1988), the latter resulting in excessive procoagulant release by monocytes. ADE can also be seen in individuals subsequently infected with another dengue virus subtype to which there are cross-reactive antibodies. One of the major problems associated with the development of vaccines to a number of viruses, for example FIPV, lentiviruses, dengue virus, AMDV, is the potential for ADE in natural virus challenges. In several situations the induction of antibodies following vaccination resulted in exacerbations of disease following subsequent virus challenge, for example FIPV (Vennema et al. 1990).

In immune complex disease there is usually a large excess of virus antigen which circulates as complexes with antibody and becomes deposited in tissues such as the kidney or blood vessels, leading to complement activation and inflammation. In persistent LCMV infection, only a weak neutralizing antibody response is generated and immune complexes become lodged in the kidney, resulting in glomerulonephritis (Oldstone et al. 1975). Chronic HBV carriers are also prone to glomerulonephritis and polyarteritis nodosa, an inflammatory disease of blood vessels initiated by deposition of virus–antibody complexes (Lai et al. 1991).

T-cell-mediated immune pathology

Damage mediated by T cells can occur via cytolysis of infected cells or by cytokine liberation. The widely used example of T-cell-mediated pathology in virus infection involves LCMV. In adult mice, infection of the CNS

Table 1 *Examples of antibody and T-cell-mediated immune pathology in virus infections*

Virus	Host	Comments
T-cell-mediated effects		
LCMV	Mouse	CD8 T-cell damage during virus infection of CNS
Hepatitis B	Humans	CD8 T-cell destruction of chronically virus-infected hepatocytes
HSV	Mouse	CD4 T-cell-mediated stromal keratitis
EBV	Humans	Infectious mononucleosis
Alcelaphine herpesvirus 1	Cattle	Malignant catarrhal fever
Theiler's murine encephalomyelitis	Mouse	CD4 T-cell-mediated demyelination
Measles	Humans	Rash dependent on T-cell immunity
Immune complex disease		
Aleutian mink disease	Mink	High risk of immune complex disease in kidney and blood vessels
LCMV	Mouse	Nonneutralizing antibody in a persisting virus infection leads to glomerulonephritis
Hepatitis B	Humans	Rash, glomerulonephritis, polyarteritis nodosa
Feline infectious peritonitis	Cat	Disseminated intravascular coagulation triggered by immune complexes
Other antibody effects		
Dengue	Humans	Antibody-dependent enhancement of infection link to dengue hemorrhagic fever
Rabies	Humans/animals	Antibody enhancement linked to early death syndrome

EBV, Epstein–Barr virus; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus.

results in severe pathological changes mediated by CD8 T cells. Treatment of mice with anti-CD8 antibodies protects against disease. The damage is not related to massive cell destruction, but is attributed to cerebral edema arising from damage to the blood–brain barrier (Buchmeier et al. 1980). CD8 CTLs are thought to underlie the damage to hepatocytes seen in chronic HBV carriers.

Delayed type hypersensitivity mediated by CD4 T cells (Th1 cells) has been associated with several types of virus-triggered immunopathology; for example, lung damage in experimental influenza virus infection (Leung and Ada 1982) and deep stromal disease of the eye in HSV-1 infection (Doymaz and Rouse 1992). CD4 T cells have also been implicated in RSV vaccination pathology. Vaccination of mice with the G protein of RSV induces a CD4 Th2 cell response, which, on challenge with RSV, initiates eosinophilic infiltration in the lung (Alwan et al. 1994). This type of pathology was identified in patients who received an ineffective formalin-inactivated RSV vaccine and subsequently became infected with RSV.

In EBV-induced infectious mononucleosis there is amplification of lymphocytes and an outpouring of cytokines (see section entitled Immune response to herpesviruses, below). An exaggerated form of infectious mononucleosis is malignant catarrhal fever seen in cattle infected with alcelaphine herpesvirus-1. This fatal disease is associated with intense proliferation of T cells resulting from a dysregulation of the cytokine response (Reid et al. 1984).

Immune-mediated pathology is a feature of infection of the CNS by a number of different viruses. Theiler's murine encephalomyelitis virus, a picornavirus, establishes a chronic infection in glial cells and induces a chronic delayed-type hypersensitivity response. Activated macrophages recruited to the CNS are believed to secrete factors such as TNF-α that kill local glial cells and result in areas of demyelination around infected cells (Chamorro et al. 1986; Clatch et al. 1986). Similarly, Semliki Forest virus (an alphavirus) causes demyelinating immunopathology, but in this case the culprit is believed to be virus-specific CD8 T cells that kill infected oligodendrocytes (Subak-Sharpe et al. 1993). Sheep infected with the maedi-visna retrovirus often develop a chronic inflammatory condition that can result in accumulation of mononuclear cells and accompanying pathological changes in various organs, including the CNS, respiratory tract, bones, and joints (Sigurdsson et al. 1962; Oliver et al. 1981).

Summary of immunopathology

The immune system is often likened to a double-edged sword, capable of efficient protection from infectious agents but sometimes causing damage to healthy tissue in the process. When the intricate series of checks and balances that regulate immune control of the host–virus relationship is upset (for example by excessive secretion of a viral protein in a persistent infection), an inappropriate response can often be deleterious. In some virus infections (for example hepatitis B, see below, section entitled Immune response to hepatitis B) the disease has a large immunopathological component, and therapy for such diseases is the focus of much research.

EXAMPLES OF IMMUNE RESPONSES TO SPECIFIC VIRUSES

General mechanisms of immunity to viruses have been outlined above; however, it is useful to consider certain case histories to illustrate how different components of the immune response are integrated. Picornaviruses are chosen as examples of acute virus infection in which antibody plays an important role. The three other virus families cause persistent and chronic infection in which the immune system has failed to clear the virus and the infection continues in the face of a continuing immune response. The outcome of HBV infection can be virus clearance or, in up to 10 percent of cases, a chronic infection with continuing virus production over long periods of time. Here, the continuing immune response causes immunopathological damage manifested as liver disease. Retroviruses and herpesviruses establish persistent infections where the virus cannot be eliminated from the host by the immune system. In the case of herpesviruses, the virus is generally in a latent form with restricted expression of viral genes presenting fewer targets to the immune system. An intact CTL response is crucial in controlling occasional reactivation and productive virus infection but does not clear latent virus. Retroviruses also establish latent infections where they do not need to transcribe viral genes but generally this is accompanied by chronic virus production. Both herpesviruses and retroviruses illustrate an equilibrium between virus replication and antiviral immunity where the virus persists but damage to the host is limited by the immune system. This equilibrium is a compromise which enables both virus and host to survive, but if breached by a breakdown in the immune system, for example in an immunosuppressed host, it can lead to serious disease. These four examples broadly cover the spectrum of viral disease ranging from acute self-limiting viral disease to life-long, chronic conditions.

Immune response to retroviruses

Retroviruses (Retroviruses and associated diseases in humans) have several unique characteristics that make recognition by host defenses particularly difficult. Their life cycle involves reverse transcription of viral RNA into DNA, which is then integrated into the

host genome. Once integrated, the virus may remain transcriptionally inactive and become methylated along with the surrounding cellular DNA. This ability to exist in the host genome without expressing viral protein makes the retrovirus invisible to the immune system. Indeed, it is estimated that 5–10 percent of the mammalian genome consists of elements introduced by reverse transcription, 10 percent of which are retrovirus-like. Most of these endogenous retroviruses cause no harm to their host, but coexist and are propagated along with host DNA and inherited by any offspring.

Vertical transmission via the germ cells is a mode of spread unique to retroviruses, and enables the virus to influence the host's immune system in early development. Retrovirus proteins expressed early in development are recognized as 'self' by the developing immune system and the responding T cells are purged from the immune repertoire. The adult animal does not therefore possess lymphocytes capable of recognizing and eliminating infected cells expressing this antigen. Ronchese and colleagues (1984) showed that mice carrying endogenous Moloney murine leukemia virus (MoMLV) did not develop antibody or cytotoxic T lymphocyte responses to the antigenically cross-reactive murine sarcoma virus. Mice infected with MoMLV had a lower than normal complement of CTL precursor cells, suggesting that clonal deletion of virus-specific cells had taken place.

In a different murine retrovirus system, mouse mammary tumor virus (MMTV) uses superantigens which bind to specific TCRs to delete reactive T cells in infected mice. This virus is transmitted from infected mothers to offspring via milk and, in susceptible mouse strains, virus integration leads to the formation of mammary tumors. The virus targets B lymphocytes and DCs where reverse transcription, integration, and gene expression lead to expression of viral superantigen (SAg) which primes an SAg specific T-cell response. The virus uses the immune system to enhance its infection in two ways – it binds directly to TLR-4 on B cells and DC resulting in the cellular activation necessary for efficient infection of B cells (Rassa et al. 2002) and in up-regulation of its receptor on DC (Burzyn et al. 2004); expression of SAg on infected B cells leads to T-cell-driven proliferation of infected cells. Continued expression of the SAg eventually leads to deletion of reactive T cells. Later in infection, the virus targets epithelial cells of the exocrine secretory organs from where it can be transmitted to offspring. Antibody is important in determining the outcome of infection. Passive immunization of susceptible mice with neutralizing antibody can prevent infection (Mpandi et al. 2003). A strong neutralizing antibody response leads to decreased mammary gland infection, development of tumors, and infection of progeny. There is a correlation between a strong antibody response and resistance to MMTV infection. Antibody plays an important role in maintaining a balance so that infection of exocrine glands, which is necessary for transmission of the virus, occurs but levels of infection are sufficiently controlled to prevent rapid tumor development (Finke et al. 2003).

Much effort has been expended in recent years on the investigation of immune responses to human retroviruses, research that has been driven partly by the HIV epidemic. HIV, a retrovirus of the genus *Lentivirus*, is therefore the most intensively studied retrovirus, although care must be taken when extrapolating from HIV to other retrovirus infections.

There is a growing body of evidence that the interaction of HIV with the immune system represents a unique situation. Acute HIV infection causes cytolytic infection of CD4 T cells, particularly those at mucosal sites, a common point of entry for the virus. The predominant CD4 T cell at those sites is the memory CD4 T cell expressing CCR5, the coreceptor for HIV in most natural infection. This results in a severe depletion of these cells which continues throughout the course of the infection. The tropism of HIV for CD4 T cells also presents particular problems for the immune system. HIV-specific CD4 T cells are particularly good targets for virus infection as activated rapidly expanding T cells are highly susceptible to HIV infection. This activation of the CD4 T-cell response presents the virus with more targets to infect and maintain the chronic infection. (Douek et al. 2003).

HIV-specific CD8 T-cell responses are present throughout the course of infection before the onset of acquired immunodeficiency syndrome (AIDS) but are unable to clear HIV infection in the majority of cases. The major problem for CD8 CTL control of HIV infection lies in the high levels of mutation rate associated with high levels of HIV replication, which results in escape epitope mutation such that at any time the CTL pool may be directed against, and indeed continuously stimulated by, epitopes which represent a very minor portion of the current HIV population. HIV infection leads to down-modulation of MHC class I on infected cells contributing to the failure of CD8 T cells to recognize and kill infected cells. Depletion of the CD4 T-cell numbers leads to loss of available CD4 T-cell help for CTL responses. Another reason for the failure of CD8 T cells to control infection may be inactivation; there is evidence that during chronic HIV infection where there is chronic stimulation of CD8 T cells, the cells loose responsiveness to antigen, for example, they often have TCRs of low functional avidity and inappropriate signaling, even those against well-conserved epitopes on one of the outer loops of gp120. This is also seen with other virus infections such as CMV and EBV. Regulatory CD4 T cells can cause functional impairment of virus specific CD8 CTLs in Friend murine leukemia virus (FrMLV) infection (Dittmer et al. 2004), and it is possible that a similar mechanism may occur in HIV infection.

HTLV-1 also targets CD4 T cells, although in this case CD8 T cells are also infected, albeit at a lower level. However, HTLV-1 is not associated with severe immunodeficiency but with adult T cell leukemia/lymphoma and a number of chronic inflammatory diseases. HTLV-1 varies little in sequence and does not present the immune system with the escape mutation scenario found in HIV infection, rendering CTL control of infection much more efficient.

An important role for antibody can be demonstrated in equine infectious anemia virus (EIAV). Episodes of disease coincide with viremia, which is brought under control by the antibody response. Disease then remits until a new virus variant emerges that cannot be neutralized by the previous antibodies; there follows another disease episode. With time, the episodes of disease become less severe, until the horse enters an asymptomatic carrier state. In this phase the disease is under effective immune control, as demonstrated by the fact that immunosuppression induces relapse.

Evasion of the antibody response is an interesting feature of HIV infection. The receptor-binding protein of HIV, gp120, is a prime target for an antibody response; however, the high degree of glycosylation and the tight conformation of this protein restrict the access of antibodies to the highly conserved receptor binding domains within the protein. In addition, the high degree of variability in the exposed faces of gp120 and the conformation-dependence of most anti-gp120 antibodies render most of the antibodies raised to be ineffective against the vast majority of the circulating virus population. One of the exposed loops, thought to contain an important neutralizing determinant, is exceptionally variable, enabling rapid escape from any effective neutralizing antibody response. Soluble gp120 is secreted in large amounts during infection, and it has been suggested that this may act as a decoy to raise an antibody response, but the conformation of gp120 on the virion is different, so the antibodies are not neutralizing. This may explain why there is a large amount of virus-specific antibody in infected individuals but the vast majority is not neutralizing.

In conclusion, while antibodies can contribute to limiting the disease process in retrovirus infection, they are generally ineffective at clearing the infection. The CTL response seems to be more important than the antibody response in protection against most retroviruses

Immune response to picornaviruses

Picornaviruses are small nonenveloped RNA viruses with a relatively simple structure consisting of an icosahedral capsid comprising four proteins and a single strand of positive-sense RNA. Members of this family are very diverse and can cause a wide range of diseases, which are usually acute infections in which the virus replicates in the host over a short time period and generally does not persist. There are some exceptions: for example, Theiler's murine encephalomyelitis virus can remain in the CNS for the lifetime of the host (Lipton et al. 1984). Others do not generally persist but can do so on rare occasions: for example, some cattle infected with foot-and-mouth disease virus go on to become chronic virus secretors.

Most picornavirus infections occur at mucosal surfaces, so the first line of defense for the host lies in the acidic mucus, which contains a number of proteases. Sensitized B cells may secrete antibody of the IgA isotype, which is transported through mucosal cells and secreted from the luminal surface. Challenge with a virus of a strain previously encountered by the immune system will result in neutralization of the virus by secreted antibody before it is able to gain access to the epithelial surface. Stimulation of IgA is the rationale behind the oral polio vaccine: it is more effective than the inactivated virus given systemically because it stimulated gut immunity directly, leading to an effective mucosal antibody response.

The replication of rhinoviruses is confined to the epithelial surface of the upper respiratory tract, and occurs so quickly that by the time the immune system has raised a response, the infection has already resolved. The object of the immune system here is to prevent reinfection. Rhinoviruses exist in hundreds of different serotypes, so there is little chance of preventing reinfection with viruses other than the initial strain. This explains the high incidence of, and poor protection against, the common cold.

In the course of systemic picornavirus infection, the virus penetrates the mucosal surface and can invade the blood stream. The viremia is not cell-associated, making the virions particularly susceptible to neutralization by serum antibody. Poliovirus infection illustrates this very well. After initial replication in the small intestine and mucosal-associated lymphoid tissue (tonsils, Peyer's patches, and lymph nodes of the neck) poliovirus can be detected in the blood. The relatively rare neurological disease (poliomyelitis) occurs following virus invasion of the CNS via the blood or through retrograde transport inside neurons. The experimental administration of neutralizing antibodies can prevent the paralytic disease in both monkeys and humans.

Both B and T cells are involved in the generation of an effective antibody response, because in the absence of T cell help only low affinity antibodies can be made, and there is no immunological memory. In recent years, the contribution made by T lymphocytes in immunity to picornavirus infections has been studied extensively. CD4 T cells involved in providing immunological 'help' for the antibody response are often cross-reactive between virus serotypes, and sometimes between different members of the picornavirus family.

The importance of T cell help can be illustrated by experiments performed in the mouse poliovirus model. Poliovirus does not normally infect mice, but using transgenic mice expressing the human poliovirus receptor they become susceptible to infection of the CNS. T cell clones have been raised against poliovirus proteins, and the transfer of these cell lines with immune B cells was able to protect the mice from lethal infection (Mahon et al. 1995). Transfer of immune B cells alone had no effect emphasizing the importance of T cells in protection. The T-cell lines secreted interferon-γ and this seemed to stimulate the preferential secretion of the IgG2a isotype antibody.

There have been several reports of CTLs in picornavirus infections (reviewed by Usherwood and Nash 1995). These are usually of the CD8 phenotype, although specific CD4 CTLs are also known to exist. Their role in the protection against picornavirus infection is unclear at present, although CD8 T cells are known to contribute to viral clearance in Theiler's virus in both susceptible and resistant mouse strains (Pullen et al. 1993; Begolka et al. 2001).

Immune responses to coxsackie B virus have been implicated in virus associated myocarditis and diabetes. Molecular mimicry (where an antiviral response cross-reacts with host antigens) is thought to be involved in the etiology of these diseases. Antisera generated against synthetic peptide sequences derived from coxsackie B3 protein and the cellular adenine nucleotide translocator cross reacted with both proteins, and antibodies which reacted with the peptides were present in patients with inflammatory cardiomyopathy. Removal of immunoglobulin from patients has been demonstrated to improve the clinical situation and, in a severe combined immunodeficiency (SCID) mouse model, human PBL have been shown to transfer disease symptoms (Schwimmbeck et al. 2004). Other evidence implicates both CD4 and CD8 T cells in coxsackie virus induced myocarditis (Henke et al. 1995). However, there is also evidence that direct viral damage is involved in disease, and limiting viral replication can limit disease (Horwitz et al. 2000). Similarly, autoreactive T cells clearly are associated with coxsackie B virus induced diabetes but there is evidence that T cells do not initiate the disease process. Phagocytosis of infected pancreatic β cells by macrophages has been observed prior to T-cell infiltration. Subsequent antigen presentation by these cells may drive an autoimmune response (Horwitz et al. 2004).

Because of their small genome (7–8.5 kb) it has been possible to map mutations that affect antibody binding sites and T-cell recognition elements for a number of picornaviruses (Usherwood and Nash 1995). In several members of the family, antibody binding sites are present on all three external capsid proteins (for example poliovirus, human rhinovirus), whereas in others, only two proteins are thought to be involved (for example, hepatitis A virus). There does not seem to be a close association between the position of T and B cell epitopes on a given virus protein.

Immune response to hepatitis B

Over 300 million people worldwide are chronically infected with HBV. HBV infection of adults is often asymptomatic, and in most cases the infection is completely cleared. However, in 5–10 percent of adults, the virus establishes a persistent infection. Neonatal infection also occurs, resulting in a degree of immunological tolerance to the virus; over 90 percent of such children become chronically infected. The persistent infection is associated with liver disease and cirrhosis in 25 percent of carriers and can progress to hepatocellular carcinoma. Reports indicate that the lifetime risk to males infected with HBV at birth of developing hepatocellular carcinoma approaches 40 percent (Beasley et al. 1981). The different outcomes of HBV infection illustrate the varied effects of alterations in the equilibrium between virus replication and the antiviral immune response.

Activation of innate nonspecific mechanisms represents a key step in the control of the initial burst of HBV replication. These mechanisms are highly efficient causing an 80 percent drop in the quantity of HBV DNA prior to the onset of the antigen-specific adaptive immune system. NK and NK-T cells are the major component of this response (Kakimi et al. 2000), but the interferon system and liver Kupffer cells play a role. During acute, self-limiting viral hepatitis, antibodies can be detected that are specific for the viral envelope (HBsAg), core antigens (HBcAg and HBeAg), and the viral polymerase (Chisari and Ferrari 1995). Antibodies to HBsAg in serum are neutralizing and are thought to play an important role in viral clearance by binding to cell free virus and preventing spread to other susceptible cells. Induction of anti-HBsAg alone during prophylactic vaccination is often sufficient to completely prevent infection.

Strong CD4 T-cell responses to HBeAg and HBcAg are seen in the peripheral blood of almost all patients with acute hepatitis. Historically, HBeAg is seen as a marker of acute infection but sensitive assays indicate replicating virus remains after removal of HBeAg. The CD4 response to the envelope is much less vigorous, the reason for which is not understood. The CD4 response in self-limiting acute hepatitis is predominantly Th1 while T-cell clones from chronically infected patients produce mainly Th2 responses (Bertoletti et al. 1997; Penna et al. 1997).

CD8 CTLs are known to be crucial in the control of the infection and strong responses to HBsAg, HBcAg and polymerase are found in patients who control HBV. Multiple epitopes are recognized. Activated HBV-specific CTL can persist long after recovery from active HBV infection, suggesting that low levels of persistent

infection maintain and are controlled by the CTL response. CD8 CTL responses in chronically infected patients are difficult to detect by classical cytotoxicity assays in both peripheral blood and the liver. Clearance in these patients via spontaneous or interferon induced remission is associated with a boost in this response. Use of MHC class I tetramer technology, which allows direct detection of virus-specific CTLs, has shown that CTLs specific for residues 18–27 of HBcAg comprise up to 1.3 percent of circulating CTLs in acutely infected patients. This is accompanied by a CTL response directed against a number of other viral epitopes. In contrast, in chronically infected HBeAg positive patients, these are barely detectable (Jung and Pape 2002). Tetramer staining shows that, in patients with a high rate of HBV replication and liver inflammation, the numbers of intrahepatic HBcAg-specific CTLs are similar to those in patients without disease, but they are accompanied by large numbers of nonspecific CD8 cells meaning that specific CTLs are present at low frequencies. Thus comparable numbers of intrahepatic virus specific CTLs could be associated with either protection or pathology raising the possibility that there is a functional defect in CTLs in chronic HBV infection (Maini et al. 1999).

HBV does not infect mice or rats but lines of transgenic mice which express HBV and can mimic chronic liver infection have been invaluable in understanding the role of the immune response in control of infection. Transfer of virus specific CTLs into these mice showed that, in addition to killing infected cells, these CTLs eliminate virus from many other infected cells noncytolytically by release of IFN-γ and TNF-α (Guidotti and Chisari 2001). Studies in chimpanzees have confirmed the importance of IFN-γ and TNF-α in removing HBV replicative intermediates from the cytoplasm and closed circular form from the nucleus of HBV infected cells (Guidotti et al. 1999). The transgenic mouse model has been used to show the importance of type I interferons in control of infection and to dissect the pathways involved in clearance. Studies show that neutrophils induce matrix metalloproteinase (MMP) which leads to recruitment of antigen nonspecific mononuclear cells. Elimination of MMPs does not affect viral clearance but prevents damage to the liver by nonspecific mechanisms (Sitia et al. 2004).

Current evidence suggests that both T cell and antibody responses to HBV are necessary to clear HBV and that CTLs act not only by lysing infected cells, but also by releasing cytokines such as IFN-γ and TNF-α that reduce the intracellular virus load without killing the infected cell. The reasons why some HBV infections of adults become chronic, while the majority are limited and cleared by the immune system, are not understood. Model systems provide support for the possibility that outcome is determined by the size of the inoculum and replication rate of the infecting virus. If this is high, then even with a fully activated immune response, viral persistence may be favored (Jung and Pape 2002). It is likely that persistence is determined by multiple mechanisms. The immune system also seems to contribute to the chronic liver pathology by causing destruction of hepatocytes, resulting in a high rate of mitosis and therefore an increased risk of damaging mutations.

Immune response to herpesviruses

There are three subfamilies in the *Herpesviridae*, each with different biological and genetic characteristics (see Herpesviruses:general properties; Alphaherpesviruses; Betaherpesviruses; Human herpesvirus 8; and Gammaherpesviruses). A central feature of the biology of these viruses is their ability to establish latent infections in either the nervous or immune system. Herpesviruses commonly have numerous immune evasion strategies which allow them sufficient time to progress from the site of primary infection and establish and maintain latency.

HSV is the prototype of the alphaherpesviruses. The natural history of HSV involves infection at mucosal surfaces followed by transmission to the peripheral nervous system where the virus remains latent in neurons. Periodic reactivation occurs with reinfection of epithelial cells which may present as recrudescent disease. HSV lesions are often more severe in immunocompromised individuals, emphasizing the importance of the immune system in controlling disease.

Components of the innate immune system including NK cells, type I interferon, and complement, play a role in the control of HSV infection in vivo but are not sufficient to prevent symptomatic infection. Antibody has been shown to interfere with virus entry to, and movement from, the nervous system (Simmons and Nash 1985), and the existence of immune evasion mechanisms directed against antibody function emphasizes the importance of antibody in neutralization of infectious virus and in antibody mediated cytoxicity. However, T lymphocytes provide the major control mechanism for both primary and recurrent infection.

DCs play a central role in stimulating the T-cell response to HSV. They are readily infected with the virus which inhibits their function as antigen presenting cells (APC) and their migration from the skin. However, infected DCs are potent producers of IFN-α which may act as a danger signal to stimulate uptake and presentation by surrounding DCs (Pollara et al. 2004). These uninfected DCs from the lesion site cross-present viral antigens and stimulate both CD4 and CD8 T cells.

A clear role for CD4 T cells is identified by their clearance of virus from the mouse epidermis. CD4 T cells are potent producers of IFN-γ which stimulates macrophage function. IFN-γ may also be important in counteracting the action of viral immune evasion molecules. HSV-specific CD4 CTL clones are present in skin

lesions and are capable of killing infected cells in vitro. The human CD4 T-cell response is broadly directed including targets from all stages of the virus life cycle (Koelle and Corey 2003).

CD8 T cells also participate in resolution of peripheral lesions (van Lint et al. 2004), but in the nervous system they assume a more important role and regulate virus replication in neurons without destroying these cells (Simmons and Tscharke 1992). Evidence suggests that within the human trigeminal ganglia, HSV infection is associated with a chronic immune reaction which influences reactivation (Theil et al. 2003). The CD8 T-cell response appears to be narrower than the CD4 response but as with CD4 T cells, the glycoproteins gB and gD are major targets (Koelle and Corey 2003).

The betaherpesviruses are typified by human and murine cytomegaloviruses, but also include human herpesviruses 6 and 7. The initial infection by CMV is via epithelial surfaces and involves a persistent or latent phase in cells of the myeloid lineage. MCMV can also establish latent infection in other cell types, probably endothelial cell or histiocytes. (Reddehase et al. 2002). cytomegaloviruses in general cause asymptomatic infection in immunocompetent hosts but are important pathogens in immunocompromised individuals.

There is a clear role for NK cells in early protection against lethal MCMV infection. An NK cell receptor which confers resistance to MCMV infection by binding directly to a viral protein expressed on the surface of MCMV infected cells and selectively killing the infected cells has been identified (Arase et al. 2002; Smith et al. 2002). The NK-cell response is limited to the first 3 days of infection and thereafter the CD8 T-cell response dominates recovery from primary infection. In MCMV, the CD8 T-cell response is against an immediate–early (IE) antigen IE1. A single antigenic peptide is recognized in the context of H-2L^{d} (MHC class I restriction molecule) of BALB/c mice. Immunization with this peptide is sufficient to confer protection against MCMV infection. Likewise, adoptive transfer of T-cell clones specific for the antigenic peptide also eliminates productive infection in most tissues (Koszinowski et al. 1990). In mice lacking CD8 T cells, CD4 T cells can take over this function. In this case, CD4 T cells derived from CD8-deficient animals can confer protection, unlike those from immunocompetent mice. Thus, the immune system appears to be able to compensate, to some extent, for lack of specific function under certain circumstances, however, this compensation does not appear to be complete. For example, mice depleted of CD4 T cells cannot eliminate virus from the salivary gland. Thus, both CD8 and CD4 cells are essential for an efficient immune response to MCMV (Krmpotic et al. 2003). CTL responses to human cytomegalovirus (HCMV) are also directed against one major target, the tegument protein pp65, although the major IE protein may be important in some individuals. CD8 T-cell responses are critical in control of HCMV infection but, like MCMV, CD4 T cells also play a role (Gamadia et al. 2003). Studies in B cell knock-out mice show that antibody is important in protecting from reactivation while CD8, CD4, and NK cells are important in both primary and recurrent infections.

The principal feature of the gammaherpesviruses is a tropism for either B or T lymphocytes. The best studied member is EBV, which targets and establishes latent infection in B cells. This virus also has the ability to transform B cells in vitro and is associated with lymphoproliferative disease. The main immunological surveillance is by CD8 T cells, which target predominantly B cells expressing the latent viral antigens EBNA-3 and LMP (Rickinson and Kieff 2001). Immunosuppression as seen in transplantation affects this balance by reducing the number of EBV-specific CD8 T cells, which results in the appearance of B cell lymphomas.

Murine gammaherpesvirus 68 (MHV-68) infection of laboratory mice has provided an opportunity for studying the immune response to a gammaherpesvirus in its natural host. This virus establishes a latent infection in B cells, DCs, macrophages, and lung epithelial cells and, like EBV, is associated with lymphoproliferative disease and an infectious mononucleosis-like syndrome (Nash et al. 2001). The availability of gene knock-out mice with targeted deletions in genes affecting immune function has made it possible to study the role of individual aspects of the immune response to MHV-68 infection. Studies in mice which lack a type I interferon response have shown that type I interferons are critical in the early control of infection (Dutia et al. 1999). MHV-68, like Kaposi's sarcoma herpesvirus and herpesvirus saimiri encodes a regulator of complement activation which has been shown to play a role in control of persistent replication and virulence in mice lacking IFN-γ responses (Kapadia et al. 2002).

During the primary infection, the virus replicates in alveolar epithelial cells. CD8 T cells clear the productive infection in the lung. A critical event is splenomegaly. This is dependent on CD4 T cells and is accompanied by a transient high load of latently infected cells. Although CD4 T cells are not essential for clearance of the initial lung infection, they are crucial for long term control of infection. Mice lacking CD4 T cells initially clear the infection, but within 3–4 months there is a recurrence of infectious virus in the lung and mice develop severe lung pathology (Cardin et al. 1996). The critical role of CD4 T cells seems to come not from providing help for antibody production or to CD8 T cells. Infection of mice lacking B cells shows that antibody is not essential for control of acute or latent infection although levels of latency are very low in these mice (Usherwood et al. 1996). Depletion of CD8 T cells and IFN-γ in B-cell-deficient mice has identified a critical role for IFN-γ produced by CD4 T cells in control of latent infection (Christensen et al. 1999). Mice lacking CD4 T cells have normal numbers of

CD8 T cells (Stevenson et al. 1998). The exact role of IFN-γ remains to be determined as mice lacking an IFN-γ response, while exhibiting pathological changes (Dutia et al. 1997), do not succumb to infection.

VIRAL STRATEGIES FOR EVADING THE IMMUNE RESPONSE

In order to survive in the host for a prolonged period a virus must either hide from or evade the antiviral immune response. As mentioned above in the section entitled Immune response to retroviruses, viruses such as MMTV that contain a superantigen, can induce a state of tolerance against themselves. A similar situation has been reported with lymphocytic choriomeningitis virus infection, in which an overwhelming infection is thought to 'exhaust' the immune response; the virus then infects the thymus so that newly emerging T lymphocytes are tolerant to virus antigens (Moskophidis et al. 1993). Some sites in the body are regarded as immunologically privileged, meaning that the ability of the immune system to respond to foreign proteins present in them is impaired. Some viruses have exploited such shelters, and preferentially infect sites such as the CNS (Fazakerley and Buchmeier 1993).

As with any rapidly replicating organism, viruses can evolve quickly in response to a changing environment. In the case of eukaryotic viruses, the immune system is a potent selective pressure, so, in order to survive, many viruses have acquired ways either of evading recognition or of obstructing the effector arms of the immune response. Most RNA viruses have high mutation rates due to errors produced by virus polymerases that lack proof-reading functions. A mutation rate of 10^{-4}–10^{-5} per base per replication cycle is typical (Holland et al. 1992). Any mutant virus that is recognized less efficiently by the immune system will dominate the virus population in the face of a stringent immune response. For example, the retrovirus HIV has a highly variable surface protein, gp120, which is the target for antiviral antibodies. Many serotypes of influenza virus exist, which have been selected by their ability to evade neutralizing antibody responses. Periodically, an antigenic shift occurs, when reassortment between two distinct influenza virus isolates result in antigenically distinct progeny that may give rise to pandemics as the virus replicates in a nonimmune population (Webster et al. 1992).

DNA viruses have less plastic genomes, often of sufficient size to accommodate genes acquired from host cells that may allow them to subvert immune attack strategies. There are also examples of convergent evolution whereby viral genes have apparently evolved to mimic cellular genes involved in immune regulation. As should be clear from the preceding sections of this chapter, many facets of the immune system are involved in the antiviral response, and the following section details how each part of the immune network may be subverted by viruses.

The literature underpinning this field has risen dramatically over the past few years. Consequently, we refer the reader to several excellent reviews that go into far greater detail on the viral genes and their mechanisms of action (Tortorella et al. 2000; Alcami and Koszinowski 2000; Alcami 2003; Benedict et al. 2002; Yewdell and Hill 2002; Goodbourn et al. 2000; Orange et al. 2002; Favoreel et al. 2003)

Inhibitors of inflammation

Inflammation is the first response to virus-induced tissue damage, which releases many cytokines necessary to attract immune cells. Vaccinia virus encodes a steroid-synthesizing enzyme, 3β-hydroxysteroid dehydrogenase, which is transcribed early in infection. It is not known which steroids are synthesized by this enzyme; several glucocorticoids are, however, anti-inflammatory and it is known that this gene contributes to viral virulence. Several poxviruses possess serine protease inhibitors (serpins), which are thought to interfere with the pathways leading to the production of lipoxygenase metabolites and IL-1β production, both of which are important pro-inflammatory factors. African swine fever virus (ASFV) directly inhibits the activation of pro-inflammatory cytokines in pig macrophages through the expression of an IκB homologue (A238L). This protein interferes with cytokine transcription by inhibiting the function of NFκB (see Alcami and Koszinowski 2000 and Tortorella et al. 2000)

Inhibition of interferon

Type I interferon released from infected cells can both induce enzymes that destroy intracellular viral nucleic acid and prevent translation of viral mRNA. Proteins made by reovirus and vaccinia virus can complex with double-stranded RNA (dsRNA) and inhibit dsRNA-dependent protein kinase (PKR) activation. Small RNAs made by adenovirus, HIV-1, and EBV are able to bind to PKR and inhibit its activation. Another protein produced by vaccinia virus acts as an alternative substrate for PKR, preventing it from phosphorylating eIF-2a. The normal cellular control mechanisms for PKR regulation are subverted by influenza virus, resulting in the repression of PKR by another cellular factor, p58. By contrast, poliovirus induces the phosphorylation and degradation of PKR. Another strategy used by viruses to disrupt interferon response involves inhibiting the activation of the JAK/STAT signaling pathway. SV5 specifically targets STAT1 for proteasome-mediated degradation. Other viruses target STAT2 (human parainfluenza virus) or JAK1(murine polyomavirus). Poxviruses have yet another mechanism for inhibiting interferon responses involving the expression

of secreted receptors or binding proteins for IFN-α/β and IFN-γ (see Goodbourn et al. 2000).

Viral interference with apoptosis

For some DNA viruses, survival in the cell is of paramount importance. To this end they have exploited strategies for disrupting apoptotic mechanisms by the use of decoy proteins with anti-apoptotic activity. Bcl-2 homologues are a feature of many herpesviruses and function as a powerful inhibitor of apoptosis. In the process of apoptosis caspase activation is a critical event. The cytokine response modifier A (CrmA) of cowpox virus is a potent inhibitor of caspase 1 and caspase 8 activity, following a variety of death inducing stimuli. Adenovirus also encodes an inhibitor of caspase 8.

Both NK cells and cytotoxic T cells kill target cells through TNF's and FasL interaction with TNF receptor (TNFR) family molecules. Poxviruses counter this by production of secreted viral TNFR which neutralizes cytotoxic cytokines. The gammaherpesviruses, Kaposi's sarcoma associated herpesvirus (KSHV) and herpesvirus saimiri (HSV) encode molecules called vFLIPS that interfere with the Fas-associated death domains (FADD)–caspase interaction blocking induction of apoptosis (see Benedict et al. 2002).

Humoral factors: complement and antibody

As mentioned in the section entitled Collectins and the complement system, above, the complement cascade is activated by a C3-convertase that can be induced by either cross-linked antibody or the surface of particular pathogens, the end result being the deposition of a membrane attack complex that causes lysis of cells or virus. Proteins encoded by some poxviruses and herpesviruses contain short consensus repeats (SCR), which are present in many complement control proteins, for example CD46 and CD55. Viral homologues of CD46, CD55, CR1, and CB4P are known to bind to C3b and C4b, inhibiting the C4b2a C3 convertase. Purified EBV virions have also been reported to accelerate the decay of C3 convertase. The *ORF4* gene of MHV-68 is present as a membrane-bound and secreted protein and functions as a regulator of complement activation. Virus lacking ORF4 is attenuated in infected mice, suggesting this viral gene product functions in vivo as a virulence determinant. Similarly, HVS possesses a protein with four SCRs that is both secreted by, and present on, infected cells and virions. HVS also has a homologue of CD59, a cellular factor that accelerates the decay of the membrane attack complex. Some viruses, HCMV and HIV, actually hijack host CD59 and incorporate this into the viral envelope. A protein present on the infected cell and on the virion of HSV-1, glycoprotein C, can bind C3b and C3bi, inhibiting initiation of the complement cascade.

Two herpesviruses, HCMV and HSV-1, are known to code for Fc receptor homologues. It is thought that these bind antibody molecules in such a way that their Fc portion cannot activate the classical complement pathway or be available for engagement by Fc receptors on phagocytes. The presence of bound immunoglobulin on the cell surface may also hinder the attachment of antibodies specific for virus antigens (see Favoreel et al. 2003; Alcami and Koszinowski 2000).

Interference with MHC function and NK cell recognition

As described in the section entitled Recognition of virus-infected cells by $CD8^+$ T lymphocytes, above, cytotoxic lymphocytes recognizing MHC class I in association with a viral peptide represent an important defense mechanism against viruses. Not surprisingly some viruses have developed ways of manipulating the CTL response, by interfering with normal antigen presentation mechanisms through MHC class I. This can be achieved at various levels in the infected cell including resistance to the catalytic processes of the proteosome, for example EBNA-1 of EBV, blockade of peptide transport by TAP proteins, for example HSV, and inhibition of maturation, assembly and migration of MHC class I molecules, for example human and mouse CMV.

The down-regulation of MHC class I expression by viruses might well disrupt CD8 T-cell recognition. However, NK cells take advantage of reduced MHC class I expression and become activated, killing virus infected cells (see section entitled NK cells in antiviral immunity). In order to thwart the attentions of NK cells, CMV encodes a MHC class I homologue (UL18 HCMV and m144 MCMV) that becomes expressed on the surface of infected cells and serves to engage Ly49 inhibitory molecules or killer inhibitory receptors (KIR) resulting in the inactivation of NK-cell killing. Another strategy used by HCMV involves the induced expression of HLA-E by a peptide generated by the viral protein UL40. HLA-E serves to protect infected cells from NK-cell attack.

Some of the DNA viruses have developed strategies to disrupt MHC class II expression. For example, adenoviruses and some herpesviruses block MHC class II transcription. HCMV US2 protein interferes post-translationally with MHC class II by translocating DRα and the DMα chain to the cytosol for proteosome-mediated degradation. HIV Nef protein interacts with the endocytic mechanisms and initiates the rapid internalization of CD4 and MHC class I molecules from the cell surface. This process brings Nef into contact with the proton pump in MHC class II containing vesicles leading to acidification and interference with peptide presentation. A similar mechanism exists for the E5 protein of papillomavirus (see Yewdell and Hill 2002; Tortorella et al. 2000; Orange et al. 2002).

Subversion of cytokine and chemokine function

The cytokine system represents the communication network coordinating the character and magnitude of the immune response. Viruses target cytokines at two levels. One involves production of viral cytokines homologues that mimic normal cytokine activity. The second involves viral cytokine receptors and binding proteins. KSHV encodes a vIL-6 and EBV produces a vIL-10, both cytokine homologues have the potential to act as growth factors for B cells with implications for the biology of these B cell tropic viruses. Poxviruses encode vTGF-β (fowlpox virus) and vSEMA, a semaphorin homologue (vaccinia virus). However, the function of these cytokine homologues has still to be determined. Both poxviruses and herpesviruses encode vTNF receptors that are secreted from infected cells and act to neutralize soluble TNF. Poxviruses also encode a variety of secreted binding proteins, for example vIL-18BP which can inhibit IL-18 induced IFN-γ and NK cell responses.

A second major immunological network involves chemokines and the role played in trafficking leukocytes to sites of inflammation and in regulating movement in and out of lymphoid compartments. The herpesviruses and poxviruses have an elaborate armory for disrupting or utilizing the chemokine network. One viral strategy involves production of viral chemokine homologues. KSHV encodes vMIP homologues that act as chemokine antagonists that attract Th2 cells and also have angiogenic activity. These activities aid the virus by disrupting the induction of protective Th1 responses and also recruiting cells to sites of infection for the purpose of virus infection.

Many gammaherpesviruses and some poxviruses encode viral chemokine receptors (vCKR). Over expression of these receptors can lead to cell transformation. A more relevant biological role for these receptors could be in transient cell proliferation and cell migration.

A third group of proteins with direct chemokine inhibitory activity are the chemokine-binding proteins. These proteins have no homology to chemokine receptors yet have evolved a high affinity for chemokines. Some binding proteins have a restricted affinity for CC chemokines, whereas the M3 protein of MHV-68 targets C, CC, CXC, CX3C chemokines. M3 functions in vivo by inhibiting lymphocyte migration to sites of infection and also plays a role in the establishment of latency, presumably by interfering with T-cell recognition of latently infected cells (for a review of this section see Alcami 2003)

CONCLUDING REMARKS

Viruses of humans and animals and their immune systems have evolved together over millions of years, each shaping the other. As protective mechanisms become more efficient and sophisticated, so do the strategies used by viruses to favor their survival. Because of their short replication time and their ability to mutate and evolve rapidly, viruses have been able to exploit niches inaccessible to immune cells. Some viruses have appropriated cellular genes coding for proteins that have a role in immune regulation, whereas others synthesize their own mimics to fool the hapless lymphocyte.

In most cases, however, the immune system can limit the damage caused during virus infections. From the perspective of the virus it is a distinct advantage if the host remains healthy, as this will assist its dissemination. Thus, acute infections (for example, rhinoviruses) may replicate quickly, causing a mild, self-limiting disease that can spread to a new host before the immune system eliminates it. The strategy adopted by viruses causing chronic infections is different: the virus can be disseminated over a much longer period of time but it must evade the immune response. Some herpesviruses (for example, HHV-6) seem to have mastered the art of persisting in a large proportion of the population for long periods without causing disease except in special circumstances. Infections such as these can be considered to have reached an amicable compromise with the host's immune system, causing little disease yet enabling the virus to spread. Viruses causing more severe disease may be those that have recently spread to their host species and have not yet evolved a mutually acceptable relationship.

Cytokines induced during viral infections	2	Directed cytokine expression with recombinant viruses	13
Modulation of the immune response	7	Conclusion	14
Role of cytokines in specific viral infections	7	References	15

INTRODUCTION

The pathological manifestation of viral disease is the result of complex interactions between the direct cytopathic effect of viral infection and the local and systemic immune responses to infection. Cytokine production is responsible for common manifestations of viral diseases such as fevers, chills, and myalgia, and the cytokine response has been associated with complications secondary to some viral infections, such as immunosuppression and dementia. It is also now clear that cytokines produced either directly in infected cells or indirectly by lymphocytes and macrophages activated by the immune response to viral proteins play an important role both in the outcome of the viral infection and in its virulence. These proteins can inhibit viral replication either directly by inducing the antiviral state in the host cells or indirectly by increasing the activation of macrophage and NK cell responses, expression of major histocompatibility antigens, initiating inflammatory responses, and stimulating the development of cytotoxic T cells, as well as the differentiation of B cells into antibody-producing plasma cells.

Recently, a new dimension of complexity has been added to the virus-mediated immune response by the finding that certain viruses have evolved mechanisms that allow them to overcome some of the components of the host-induced cytokine response by producing proteins that mimic cytokines or their receptors. Other viruses have developed defense mechanisms that enable them to interfere with the transcriptional activation of cytokine genes or with their mechanisms of action. Thus, many of the viral genes that are not required directly for viral replication may be essential for pathogenicity of the virus in vivo. These aspects of viral escape from immune surveillance are discussed elsewhere in this volume (The immune response to viral infections).

Local immune responses seem to be especially important in the development of cell-mediated immunity and antibody production. During the early stages of viral infection, innate cytokines such as interferon (IFN)-α and -β play a critical, but not overlapping role, in the stimulation of NK cell functions. The cytokine expression profile defined as Th1, associated with the production of IFN-γ, interleukin (IL)-2, and IL-12, leads predominantly to cell-mediated immunity. The Th2 profile of cytokine expression, in which IL-4, IL-5, IL-6, and IL-10 are produced, results in the production of virus-specific antibodies. Depending on the type of infection, the T-helper (Th)1 or Th2 response can be local or systemic, as has been suggested for human immunodeficiency virus type 1 (HIV-1) infection. This chapter deals with the role of cytokines in the early inflammatory responses and the outcome of viral infection. Particular emphasis is given to the viral infections of the central nervous system (CNS), HIV-1, herpesvirus and hepatitis virus infections, where there is clear evidence of a close relationship between cytokine production, viral replication, and pathogenicity. The use of recombinant viruses

to examine the effect of a selected cytokine is also discussed. Finally the current knowledge of the immune response triggered by the ligation of Toll receptors is summarized, since there is accumulating evidence that these are recognized not only by bacterial envelopes and double-stranded RNA and DNA, but also by viral proteins.

CYTOKINES INDUCED DURING VIRAL INFECTIONS

Interferons

IFNs have a broad antiviral action against many viruses and play a critical role in innate immunity. They are the earliest defense mounted by the host during viral infection, until immune mechanisms can be fully engaged. An important element of the extensive cytokine network, IFNs also play a crucial role in the modulation of the immune system (de Maeyer and de Maeyer-Guignard 1991). Functionally, IFNs can be divided into two groups: type I IFNs, IFN-α, IFN-β, IFN-ω and IFNκ and type II IFN, IFN-γ (Table 1). Recently, a new group of antiviral proteins that are induced as response to viral infection and share the antiviral properties with type I IFNs, IFNλ (Kotenko et al. 2003; Sheppard et al. 2003) has been identified.

Normally silent, IFN A and B genes are rapidly induced in response to viral infection, while a distinct feature of IFNκ is its constitutive expression. A deficiency in the IFN system can lead to fulminate viral disease (Levin and Hahn 1985). Human type I IFN genes lack introns and map to the short arm of chromosome 9. There are more than 20 IFN-α genes and pseudogenes, five IFN-ω genes, but only one IFN-β and IFNκ gene (Diaz 1995). The single IFN-γ gene contains three introns and maps to the long arm of chromosome 12. Whereas IFN-α is a family of nonglycosylated monomeric proteins (Allan and Fantes 1980), IFN-β, IFN-ω and IFN-γ are *N*-glycosylated. Functionally, IFN-β is a dimer, whereas IFN-γ is a tetramer. Synthesis of IFN-α takes place mainly in cells of lymphoid origin, while IFN-β is synthesized in fibroblasts, epithelial cells, and macrophages. IFN-ω is induced in leukocytes and trophoblasts and IFNκ is expressed in keratinocytes and dendritic cells. Production of IFN-γ is a specialized function of T lymphocytes, although NK cells and macrophages can produce IFN-γ as well. Competitive binding studies (Merlin et al. 1985) indicate that a common receptor for IFN-α, -β and -ω, as well as the receptor for IFN-γ, are encoded by genes mapping to chromosome 21.

IFNs exert their multiple effects through binding to cell-specific receptors and receptor-mediated transduction pathways results in the induction of IFN-stimulated genes (ISG) (Darnell et al. 1994). The type I IFNs, IFN α, β, ω and κ bind to a common receptor consisting of two subunits that both map to human chromosome 21. Type II IFN, IFN-γ binds to a distinct set of receptors that also consists of two subunits. The recently identified IFN λ binds to a heterodimeric receptor that consists of IL-10Rβ and orphan class II receptor chain, IL-28Rα (Sheppard et al. 2003; Kotenko et al. 2003). The gene arrays analysis has shown that the type I IFN binding to its receptor results in a major transcriptional

Table 1 *Human interferons*

Name	Genes	Proteins	Producer cells	Effect
IFN-α	>20	Nonglycosylated	Lymphoid cells	Antiviral state
	No introns	166 aa	Macrophages	ISG induction
	Chromosome 9	Monomer		MHC I induction
IFN-β	1	*N*-glycosylated	Fibroblasts	Antiviral state
	No introns	166 aa	Epithelial cells	ISG induction
	Chromosome 9	Dimer	Macrophages	MHC I induction
IFN-ω	5	*N*-glycosylated	Leucocytes	Similar to IFN-α
	No introns	172 aa	Trophoblasts	
	Chromosome 9	...		
IFN-γ	1	*N*-glycosylated	T cells	2′,5′-OAS induction
	3 introns	146 aa	Macrophages	IL-1 enhancement
	Chromosome 12	Tetramer	NK cells	MHC I induction, MHC II induction
IFNκ	No introns	180 aa	Keratinocytes, DC	Antiviral
	Chromosome 9			Cytokine induction
IFN λ	3	Glycosylated	Most tissues	Antiviral activity
	6 introns			2′,5′-OAS, Mx induction
	Chromosome 19			MHC I induction

aa, amino acid; DC, dendritic cells; IFN, interferon; ISG, interferon-stimulated gene; MHC, major histocompatibility complex; 2′,5′-OAS, 2′,5′-oligoadenylate synthetase.

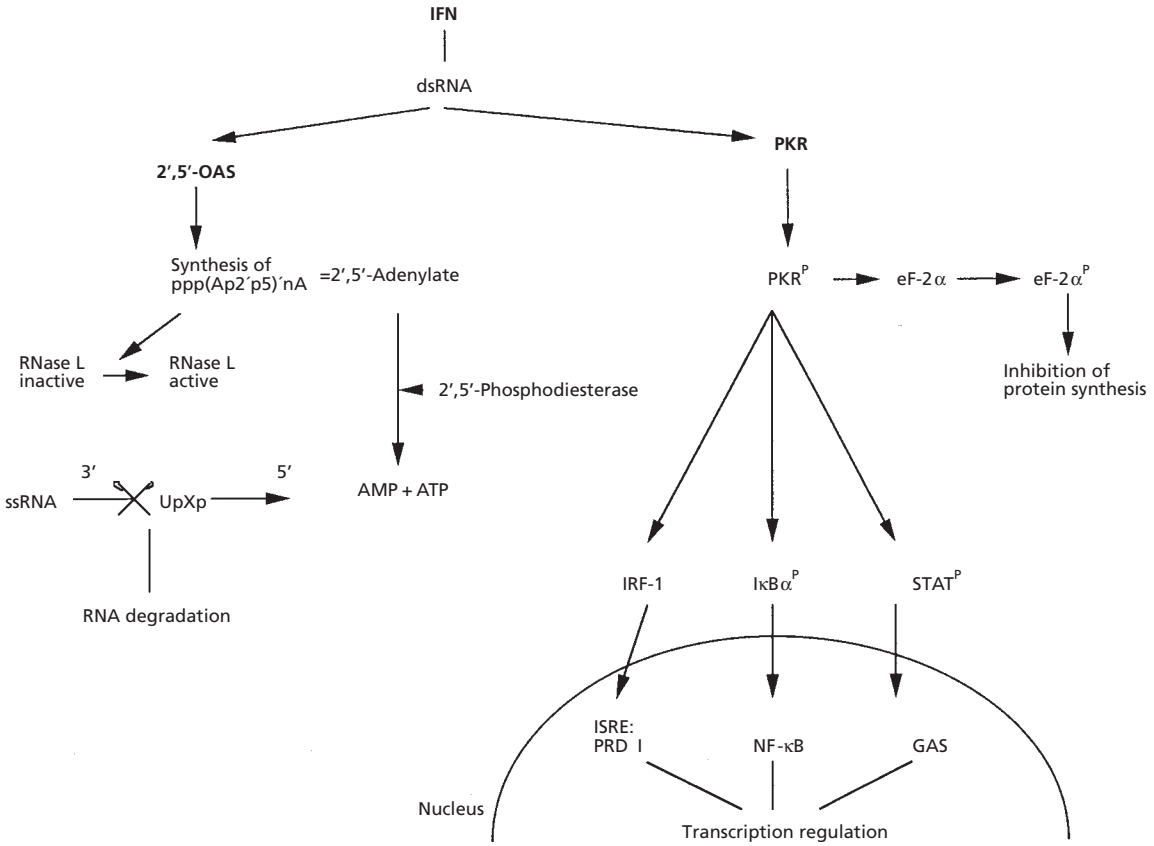

Figure 1 *Double-stranded (ds) RNA-dependent interferon-stimulated antiviral activities. GAS, γ-interferon-activated sequence; IκBα, inhibitor protein binding NF-κB transcription factors; IRF-1, interferon responsive factor 1; ISRE/PRD 1, interferon-sensitive response element/positive regulatory domain 1; P, phosphorylated; STAT, signal transduction activator transducer; UpXp, (by convention) a short RNA sequence in which the phosphorylated base uridine is followed by any other phosphorylated base (A, C, or G).*

activation and expression of more than 100 cellular genes, including genes encoding proteins with antiviral properties, growth-regulating proteins, and components of ubiquitin pathway (Samuel 1991; Malakhova et al. 2003).

The IFN-induced signaling pathway involves activation of several Janns-activated kinase (JAK) kinases that are associated with IFN receptors and by the consequent tyrosine phosphorylation cascade they activate the pre-existing transcriptional factors called signal transducers and activators of transcription (STAT). Phosphorylated STAT proteins, bind to importin and accumulate in the nucleus assembled in multimeric complexes where they interact with interferon-responsive elements present in the 5′ flanking region of interferon-stimulated genes (ISGs) (Levy 1995). Although both IFN-α and -β bind to the same receptors induction of distinct gene(s) by IFN-β was reported suggesting a possible existence of yet unidentified cofactor. Type I and type II IFNs are essential for antiviral defense and they are not functionally redundant (Muller et al. 1994). Both types of IFNs modulate the expression of major histocompatibility complex (MHC) antigens. It is via that mechanism that IFN-α/β increases the susceptibility of fibroblasts infected with vaccinia virus or lymphocytic choriomeningitis virus (LCMV) to cytotoxic T lymphocyte (CTL) lysis (Bukowski and Welsh 1985). Type I and type II IFNs modulate MHC II antigen expression, IFN-γ and tumor necrosis factor (TNF)-α are the most powerful inducers of MHC II antigens. IFN-γ enhances expression of MHC II antigens on accessory cells, stimulates the interaction of these cells with T cells and promotes CTL development. Murine IFN-α and IFN-β can block IFN-γ-mediated class II antigen up-regulation (de Maeyer and de Maeyer-Guignard 1991).

IFNs act via a paracrine loop. Virus-induced IFNs are secreted by the cell and activate neighboring cells into an antiviral state characterized by the expression of a number of ISGs. Several of the proteins encoded by ISGs have direct antiviral activities (Samuel 1991). The antiviral activities of 2′,5′-oligoadenylate synthetase (2′,5′-OAS), PKR protein kinase, and Mx proteins have been well characterized (Figure 1). The 2′,5′-OAS pathway comprises three enzymes. 2′,5′-OAS, upon activation by double-stranded RNA, polymerizes ATP into pppA(2′p5′A)n, (2′,5′A) (Kerr and Brown 1978). 2′,5′A in turn activates a cellular endonuclease, 2′,5′-OAS-dependent RNaseL (Williams and Silverman 1985;

Zhou et al. 1993). RNaseL is present in the cells in an inactive form. When activated by 2′,5′A, it degrades both cellular and viral RNAs at UU or AU nucleotides. 2′,5′-Phosphodiesterase (Lengyel 1982) catalyzes the degradation of 2′,5′A. Expression of 2′,5′-OAS (40 kDa) in cells leads to the establishment of an antiviral state which results in the selective inhibition of the replication of picornaviruses, such as mengovirus and encephalomyocarditis virus (Chebath et al. 1987). The antiviral effect of the 2′,5′-OAS system is specific for picornaviruses and no inhibition of VSV or HSV-1 has been observed.

Activation of the IFN-induced kinase, PKR, depends on the presence of dsRNA. The phosphorylation of the α subunit of protein synthesis initiation factor eF-2 (Samuel 1979; Berry et al. 1985) by PKR has been implicated in the inhibition of viral protein synthesis (Pathak et al. 1988). The crucial role of PKR in the antiviral effect of IFN is further indicated by the observation that a number of viruses have developed mechanisms to negate the function of PKR. Among these adenovirus encodes small RNAs, VA-RNA, which are synthesized in the late stages of the replication cycle and interfere with the activation of PKR and phosphorylation of eF-2a (Davies et al. 1989). Vaccinia virus encodes a specific PKR inhibitory factor (SKIF) (Akkaraju et al. 1989).The reovirus encoded protein G3 binds dsRNA and inhibits the activation of PKR by competing for dsRNA (Imani and Jacobs 1988). Poliovirus, on the other hand, inactivates PKR by inducing the autophosphorylation of PKR and its subsequent degradation. In addition to its antiviral effect PKR is also implicated in the control of cell proliferation (Samuel 1991).

The Mx proteins are GTPases and the molecular mechanism and the antiviral activity of Mx proteins depends on specific MX protein, its cellular localization of the type of viral infection. The antiviral activity of MX is dependent on its oligomerization, GTP binding, and hydrolysis. Athough originally identified as inhibitor of influenza virus infection (Haller et al. 1979; Samuel 1991). It has recently been shown that the Mx protein inhibits also additional RNA viruses, including measles and hantavirus replication (Frese et al. 1995).

The IFN induced RNA-specific adenosine deaminase-ADAR1 catalysis A-I editing and recent studies described an extensive A-I (G) hypermutation editing for several viral RNA.

ISG 20 was recently identified as single-stranded RNA endonuclease and its role in the antiviral effect of IFN against VSV and EMC was implicated (Espert et al. 2003).

These and possibly other IFN-regulated proteins confer on IFN its broad antiviral spectrum. In addition to the above-described IFN-mediated viral inhibition, IFN has been shown to block other steps of the viral life cycle. IFN-α inhibits cytomegalovirus (CMV) at the level of transcription of viral immediate–early (IE) genes, in particular that of the major genes *IE1*, *IE2*, and *IE3* (Martinotti and Gribaudo 1992). Whereas both IFN-α and IFN-γ inhibit adenovirus early gene expression, only IFN-γ inhibits late transcription (Mistchenko et al. 1989). IFN-α inhibits HIV-1 at many steps of its life cycle, but predominantly at the level of reverse transcription in acutely infected T cells and monocytes (Shirazi and Pitha 1992, 1993) and at the level of virus assembly in chronically infected cells (Pitha 1991). Inhibition of virus assembly and maturation is the major mechanism by which IFN blocks the replication of murine retroviruses (Pitha 1980). Stimulation of HLA class 1 expression on measles virus infection is mediated by IFN-β.

The availability of purified and recombinant IFN preparations has made possible the clinical use of IFN-α for the treatment of papillomavirus infections of the larynx, the anogenital regions, and the skin (Fingerote et al. 1995). IFN-α has also become the treatment of choice for chronic hepatitis B and hepatitis C virus infections. Hepatitis virus replication is inhibited by IFN-induced 2′,5′-OAS in mouse peritoneal macrophages. The antiviral effect of 2′,5′-OAS is not sufficient, however, to prevent the hepatocellular injury associated with hepatitis virus infection (Fingerote et al. 1995). Intranasal use of IFN-α for rhinovirus infections causes substantial damage to the nasal mucosa (Finter et al. 1991; Gutterman 1994). The major role of IFN-γ in antiviral defense is to modulate the immune response to viral infection. IFN-γ has, however, a direct antiviral effect, possibly through the induction of 2′,5′-OAS (de Maeyer and de Maeyer-Guignard 1991). In mice, IFN-γ controls T cell-mediated viral clearance in acute cutaneous and ocular infection with herpes simplex (HSV-1) and in poxvirus infection. In macrophages, IFN-γ inhibits HSV-1 and vaccinia virus replication by inducing the production of nitric oxide in the infected cells (Karupiah et al. 1993). The growth of hepatitis virus is restricted in mice by IFN-γ-activated macrophages (Vassao et al. 1994). IFN-γ is also necessary for a normal antigen-specific immunoglobulin G2a response, as demonstrated in mice lacking the IFN-γ receptor (Huang et al. 1993). Intraperitoneal infection with mouse cytomegalovirus or herpes simplex virus (HSV) results in inflammatory infiltrates, consisting mainly of macrophages with increased expression of IFN-γ and TNF-α. CMV titers are increased in IFN-γ-depleted mice and in mice with severe combined immunodeficiency (SCID) (Heise and Virgin 1995). The antiviral effect of IFN-γ has also been demonstrated by the observation that the replication of recombinant vaccinia virus expressing IFN-γ is markedly inhibited, compared to that of wild-type virus (Ramshaw et al. 1992). The virulence of poxvirus infection is increased in mice lacking IFN-γ, and one of the myxoma virus genes implicated in the growth of the virus in vivo encodes the IFN-γ receptor (Upton et al. 1987).

Viruses have, however, evolved mechanisms to evade the antiviral effects of IFN. Many viruses have developed mechanisms by which they negate the function of RNA-activated protein kinase (PKR) (Reich et al. 1988). By contrast, flaviviruses (e.g. West Nile virus and Kunjin virus) induce expression of intercellular adhesion molecule-1 (ICAM-1) by two distinct mechanisms. First, induction is mediated by type I IFNs and occurs only in quiescent fibroblasts in G0 phase; the second induction is cytokine-independent and occurs within hours of viral challenge. The induction of cell–cell contact via ICAM-1 expression early in infection may significantly enhance the ability of the virus to spread before the immune response is triggered (Shen et al. 1995).

Cross-talk between IFNs and other cytokines is an essential component of the immune response

The experimental evidence suggests that both the innate and the acquired immune response involves cytokine-mediated amplification and cross-talk network. Thus the antiviral response seems to undergo the amplification step in which the IFN-β induced during the initial response to infection stimulates the expression of transcription factors that are required for the induction of expression of the IFN-α family of proteins resulting in much robust antiviral response.

In addition to the antiviral function, the IFN-α/β-mediated signaling pathway affects also the immune responses through the modulation of expression of several cytokines. Thus, while IFN-γ promotes expression of IL-12, IFN-α/β down-regulates IL-12 expression in monocytes and dendritic cells. IFN-α/β mediates induction of IL-15 that promotes survival of activated NK cells and their accumulation (Biron 2001). In human cells but not in mice, IFN-α/β activates IFN-γ and Th1 development of $CD4^+$ cells. Altogether these results indicate that IFN-α/β stimulates the signaling pathway for the innate regulation of adaptive immunity.

Tumor necrosis factor

TNF-α (cachectin) and -β (lymphotoxin) are two related peptides encoded by linked genes mapping within the MHC (Spies et al. 1986). Although TNF-α is secreted mainly by macrophages/monocytes and TNF-β by T cells, they compete for a common receptor. TNF-α, like IFN, can establish an antiviral state, and TNF-α-mediated induction of 2′,5′-OAS has been demonstrated in a number of cell lines (Mestan et al. 1988). IFN-γ and IFN-β synergize with TNF-α to increase levels of 2′,5′-OAS and viral inhibition (Mestan et al. 1988). Studies in vivo, with mice as a model for encephalomyocarditis virus (EMCV) infection, have shown that TNF-α alone is not sufficient to inhibit viral replication, but requires combined treatment with IFN-γ (Czarniecki 1993). The same requirement has been observed with murine CMV (Anderson et al. 1993). The direct antiviral effect of TNF-α has been well documented with recombinant vaccinia virus expressing TNF-α (Ramshaw et al. 1992). In contrast, the replication of retroviruses, such as simian immunodeficiency virus (SIV) and HIV, is activated by TNF-α (Lairmore et al. 1991). Although IL-6 mRNA levels are increased in response to TNF-α, IL-6 alone does not seem to contribute to the TNF-α-induced antiviral state (Jacobsen et al. 1989).

Both RNA and DNA viruses can induce TNF-α expression in peripheral blood mononuclear cells (PBMC) and macrophages. Influenza virus increases TNF-α mRNA levels in monocytes (Nain et al. 1990), respiratory syncytial virus (RSV) stimulates TNF-α secretion in macrophages (Franke-Ullman et al. 1995) and human herpesvirus-6 (HHV-6) triggers TNF-α secretion in PBMCs (Flamand et al., 1991). TNF-α secretion by PBMCs from patients with chronic hepatitis B virus infection correlates with the level of virus replication. TNF-α inhibits replication of vesicular stomatitis virus (VSV) in WISH cells and replication of EMCV in HeLa cells. Another mechanism by which TNF-α limits viral spread is by enhancing viral cytotoxicity. TNF-α induces cytolysis of HSV-1 and HSV-2-infected rat embryo cells (Koff and Fann 1986). Cytolysis is also observed with either TNF-α or TNF-β in VSV or adenovirus-2-infected A549 cells. In vivo, however, adenovirus *E1A* gene encodes a 14.7 kDa protein which suppresses TNF-α-mediated cytolysis and thereby allows escape from the antiviral effects of TNF-α (Laster et al. 1994). Furthermore, co-expression of the adenovirus 14.7 kDa protein in a recombinant vaccinia virus expressing TNF-α inhibits the TNF-α-mediated attenuation of vaccinia virus virulence (Tufariello et al. 1994). Also, one of the genes in the terminal repeat of myxoma virus involved in modulating the replication of the virus in vivo encodes a soluble TNF-α receptor. Because induction of TNF-α is an essential part of the cellular defense against myxoma virus infection, the virus is able to neutralize the effect of TNF-α. Induction of TNF-α, as well as IFN-γ and IL-1 during dengue virus infection in macrophages may result in permeability of vascular endothelial cells and plasma leakage, which are characteristic of the hemorrhagic fever secondary to dengue virus infection. Not all viruses, however, can induce TNF-α. HSV-1, for instance, is a strong inducer, whereas Epstein–Barr virus (EBV) down-regulates the levels of TNF-α mRNA and protein in PBMCs (Gosselin et al. 1992).

Interleukin-1

The interleukin-1 (IL-1) family is composed of two cytokines, IL-1α and IL-1β, and one inhibitor, IL-1 receptor antagonist (IL-1ra). Although IL genes are highly

conserved across species, they share little homology with one another and their regulation is different. Both IL-1α and IL-1β are synthesized as membrane-bound precursors of 270 aa, cleaved by proteases to yield circulating soluble proteins. IL-1 is produced mainly by macrophages, but T and B cells, dendritic cells, fibroblasts, epithelial cells, and astrocytes can synthesize IL-1 as well. IL-1 has no direct antiviral activity but, together with IL-2, induces IFN-γ synthesis and thus contributes indirectly to the antiviral immune response. IFN-α has been reported to down-regulate IL-1β in bone marrow stromal cells, while stimulating expression of the IL-1 receptor, thereby contributing to the myelosuppression associated with viral infections (Arman et al. 1994). Not all viral infections result in the induction of IL-1. Whereas influenza virus induces substantial IL-1 activity in macrophages, RSV induces IL-1 inhibitor activity (Roberts et al. 1986). In situ hybridization studies have shown that HIV-1, herpesviruses, EBV and CMV, adenovirus, and chronic hepatitis B virus (HBV) infection induce *IL-1β* and *IL-6* genes, not, however, in the infected cells themselves but in macrophages and epithelial cells adjacent to the infected cells (Devergne et al. 1991). IL-1, together with TNF-α and IL-6, is a key cytokine expressed during inflammation. In mice, cerebral expression of IL-1α and -1β and TNF-α correlates with the onset of neurodegenerative processes secondary to scrapie infection (Campbell et al. 1994). Although both adult T cell leukemia (ATL) and human T-cell lymphotrophic virus type 1 (HTLV-1)-associated myelopathy/tropical spastic paraparesis (HAM/TSP) are associated with HTLV-1 infection, the difference in virus-induced cytokine expression may underlie the differences in pathogenesis between the two diseases: IFN-γ, TNF-α, and IL-1β expression is induced in HAM/TSP, whereas elevated levels of transforming growth factor β (TGF-β) are secreted by leukemic cells in ATL (Tendler et al. 1991).

Interleukin-6

IL-6 is produced by T and B cells, macrophages, fibroblasts, and endothelial cells. During viral infection, *IL-6* seems to play an essential role in antibody production, since it induces B cells to differentiate into antibody-producing cells. Mice with targeted disruption of the *IL-6* gene have a reduced number of IgA-producing cells. Expression of IL-6 enhances systemic and mucosal antibody responses in mice infected with a recombinant fowlpox virus expressing influenza virus hemagglutinin and IL-6 (Ramsay et al. 1994). In contrast, IFN-γ expression in those animals inhibits antibody responses, but not cell-mediated immunity (Leong et al. 1994). Both RNA and DNA viruses induce IL-6 expression. Thus, HTLV-I transactivator protein, Tax, induces IL-6 expression through the direct activation of the IL-6 NF-κB site (Mori et al. 1994). Chronic virus-producing, but not chronic latent, hepatitis B infection increases serum IL-6 activity, and IL-6 levels are further enhanced during acute exacerbation of the disease (Kakumu et al. 1991). Dengue virus, which is transmitted through mosquito bites, induces a rapid expression of IL-6 in fibroblasts, as well as granulocyte/macrophage colony stimulation factor (GM-CSF) and IFN-β. IFN protects uninfected cells from infection and limits virus spread (Kurane et al. 1992). Elevated serum levels of IL-6, IL-1 and TNF-α are also found in patients with dengue hemorrhagic fever (Hober et al. 1993). HIV-1 transactivating protein tat can induce IL-6 production in uninfected PBMCs in vitro and IL-6-dependent IgG and IgA synthesis (Rautonen et al. 1994). In the presence of IL-4, HIV-1 infection induces an autocrine IL-6 loop in B cells. Acquired immune deficiency syndrome (AIDS)-associated Kaposi's sarcoma positive PEL cells express the IL-6 receptor and use IL-6 as an autocrine growth factor (Masood et al. 1994). Macaque monkeys infected with a lethal variant of SIV (SIVsmm/PBj-14) show a marked increase in both IL-6 mRNA in inflamed tissues and IL-6 protein in serum (Birx et al. 1993).

Virally induced IL-6 participates in inflammatory reactions together with IL-1 and TNF-α. Live or inactivated RSV induces increased levels of IL-6, as well as TNF-α mRNA in alveolar macrophages. The combination of these two cytokines (IL-6 and TNF-α) does not seem, however, to have a direct antiviral effect but modulates the inflammatory response to RSV infection (Becker et al. 1991). In a similar manner, live or UV-irradiated coxsackie virus B3 (CVB3) stimulates the release of IL-6, IL-1, and TNF-α in infected human monocytes, and supernatants from CVB3-infected monocytes are cytotoxic to heart cells, suggesting that these cytokines induced by viral infection may contribute to the pathology of CVB3-induced myocarditis. In patients with cerebrospinal inflammation, however, it is acute bacterial meningitis and not viral meningitis (such as is caused by mumps virus) that is associated with increased IL-6 activity (Torre et al. 1992).

Interleukin-7, 8, and 10

IL-7 is a 177 aa protein secreted by thymic stroma cells and acts as a T-cell growth and differentiation factor and a macrophage activation factor. IL-7 also augments an *env*-specific CTL response in HIV-1 infected individuals in a dose- and time-dependent manner and promotes the maturation of precursor CTLs independently of IL-2. IL-8 is a member of a large family of factors secreted by macrophages and endothelial cells which act as mediators in inflammation. Constitutive expression of IL-8 and IL-6 by tracheobronchial and nasal epithelial cells is significantly increased upon viral infection (Adler et al. 1994). RSV, in particular, induces the release of IL-8 and IL-6 in the human epithelial cell line A549 in a time- and viral load-dependent manner. In addition, proinflammatory cytokines, such as TNF-α and IL-1

Table 2 *Virus-induced modulation of cytokine effects*

Virus	Viral gene	Cellular homologue	Effect
Poxviruses	MGF	EGF/TGF-α	Cell growth
	T2	TNF receptor	TNF inhibition
	T7	IFN-γ receptor	IFN-γ inhibition
	Unmapped	IL-1 receptor	IL-1 inhibition
EBV	BCRFI = vIL-10	IL-10	Escape from immune surveillance
Adenovirus	E1A = 14 ± 7 kDa protein	...	Suppresses TNF lysis
	E1B = 19 kDa protein		Counteracts TNF effects
	VA RNA		Inhibits IFN-α/β

synergistically enhance IL-8 secretion in RSV-infected A549 cells (Arnold et al. 1994). IL-10, appropriately termed cytokine synthesis inhibitory factor, inhibits the production of IFN-γ, and secretion of IL-1, IL-6, and TNF-α by macrophages. An open reading frame from EBV, *BCRFI*, shows extensive homology with IL-10, and it has been suggested that viral IL-10 expression enables infected cells to escape from immune surveillance (Moore et al. 1990) (Table 2).

Interleukin-4 and 12

IL-4 is a 20 kDa glycoprotein, B cell growth and differentiation factor which is secreted by Th2 cells and plays an essential role in the initiation of humoral immunity. IL-12, also known as NK cell stimulatory factor (Kobayashi et al. 1989), is a heterodimer which stimulates IFN-γ production. It has become clear now that IL-12 and IL-4 play pivotal roles in the differentiation of naive T cells into Th1 and Th2 subsets. Although viruses tend to trigger cell-mediated immunity, not all do so. CNS infection with live measles virus induces IL-4 expression and Th2 cell activation (Ward and Griffith 1993). Sindbis virus, which causes acute encephalomyelitis in mice, also triggers a Th2 response in the brain, characterized by increased expression of IL-4, IL-16, IL-10, and TGF-β in the brain (Wesselingh et al. 1994). IL-4 and IL-12 also seem to have an enhancing effect on HIV-1 replication, as is described in detail later under Role of cytokines in specific viral infections. The role of IL-4 and IL-12 in the Th1 and Th2 immune responses is explored more fully later in this chapter (see Th1–Th2 shift, below).

MODULATION OF THE IMMUNE RESPONSE

Th1–Th2 shift

As mentioned earlier, T lymphocytes are required for cell-mediated immune responses and antibody production by B cells. This dual role is controlled by two distinct Th cell subsets. Th1 cells produce IL-2 and IFN-γ and direct cell-mediated immunity, whereas Th2 cells produce IL-4, IL-6, and IL-10 and promote antibody production for humoral immunity. IL-12, secreted by macrophages and B cells, stimulates the production of IFN-γ in T cells and NK cells. IL-12 has been shown to act directly on $CD4^+$ naive T cells derived from T receptor transgenic mice to induce IFN-γ production and T-cell differentiation towards Th1 development (Seder et al. 1993). In contrast, IL-4 has been shown, in the same system, to drive Th2 cell development and Th2-specific cytokine expression. Moreover, Th2-specific cytokines, IL-4 and IL-10, inhibit IL-12 production in human macrophages and, thereby, the Th1 response. As both IL-12 and IL-10 are produced by macrophages, these can either promote or inhibit Th1 cell development, depending on the relative production of either cytokine by these cells. IFN-α stimulates production of Th1 cells and IFN-γ blocks Th2 development (Sher et al. 1992). Th1 and Th2 responses play important roles in viral clearance. In mice, Th1 clones are protective against lethal challenges with influenza virus, whereas Th2 clones are not protective and delay viral clearance (Graham et al. 1994). A switch from Th1 to Th2 responses has been suggested as playing a role in HIV infection and progression to AIDS. According to this model, HIV-specific T cell responses of the Th1 type would keep the infection under control. An increased viremia would result in a Th2 response, antibody production, and progression to AIDS. In this model, any stimulus or pathogen that could promote a switch from Th1 to Th2 would act as a cofactor in the progression to AIDS. If this model holds true, treatment with exogenous IL-12 might support and maintain Th1 cell function and thus delay the progression of the disease. This question is being explored in a number of clinical trials.

ROLE OF CYTOKINES IN SPECIFIC VIRAL INFECTIONS

HIV replication and pathogenicity

Human immunodeficiency virus (HIV-1) is recognized as the etiological agent of the slowly

progressing immune deficiency in humans that culminates in the development of AIDS (Barré-Sinoussi et al. 1983). The rate of progression of this lentiviral infection and the onset of the disease seem to depend on viral determinants (multiplicity of infection, virus strain, or isolate), the interaction of HIV-1 with the host immune system and a number of cofactors, such as secondary viral and bacterial infections, cytokines, or stress factors. The primary targets of HIV-1 infection are $CD4^+$ cells, especially T cells and the cells of the myeloid lineage, monocytes and macrophages.

Initial infection with HIV-1 is followed within 3–5 weeks by an acute phase characterized by influenza-like symptoms, lymphadenopathy, plasma viremia, and a significant decrease in circulating $CD4^+$ cells. During the acute phase, HIV-1 disseminates to other tissues, particularly to the lymph nodes. The generation of an immune response at those sites results in the suppression of HIV-1 levels in the blood and restoration of the $CD4^+$ cells. Infection then enters a state of clinical latency, when little virus can be detected in plasma. However, viral replication takes place in lymph nodes, where it continues to infect the $CD4^+$ cells (Pantaleo et al. 1993). Recent studies from several laboratories have shown that, during these seemingly asymptomatic stages, virus-infected T cells are rapidly cleared from the circulation by the vigorous immune response (Coffin 1995; Ho et al. 1995). The high replication rate of HIV-1 results in the death of lymphocytes that are continuously being replenished by the immune system. This leads to the gradual decrease in $CD4^+$ T cells and the deterioration of the immune response. In the final stages of infection, HIV-1 reappears in the blood as a consequence of a breakdown of lymph node ultrastructure; the paucity of $CD4^+$ cells and the lack of appropriate immune response facilitate numerous opportunistic infections and the development of neoplasia.

Effect of HIV infection on cytokine gene expression

The production of cytokines by macrophages and T cells is part of the inflammatory response to viral infection, which is essential for lymphocyte activation, generation of cytotoxic cellular responses, and antibody production.

Increased levels of TNF-α, IL-1, IL-6, transforming growth factor β (TGF-β), and IFN-α and IFN-β have been found in the sera of AIDS patients (Birx et al. 1990; Breen et al. 1990). However, in vitro, the spontaneous and lipopolysaccharide (LPS)-stimulated production of TNF-α, IL-1, and IL-6 does not seem to be significantly different in peripheral blood lymphocytes (PBL) isolated from AIDS and uninfected donors (D'Addario et al. 1990; Molina et al. 1990; Yamato et al. 1990). In another set of reports, an increase in TNF-α production in PBLs has been observed with the progression of HIV-1 infection (Rossol et al. 1992). An increase in the relative levels of TNF-α, IL-1, and IL-6 mRNAs has also been observed in LPS-stimulated alveolar macrophages isolated from individuals with AIDS, compared with the levels of mRNAs present in macrophages isolated during the early stages of HIV infection. Polyclonal activation of B cells (Reickmann et al. 1991) and increased levels of IL-6 may be associated with the higher frequency of B cell malignancies seen in AIDS patients.

Increased levels of IFN-α and IFN-γ (acid-labile IFN-α) were found both in pre-AIDS and in AIDS patients, but the frequencies and levels were higher in AIDS patients (Künzi and Pitha 1995). Elevated levels of IFN-α serum have been associated with a poor prognosis (Voth et al. 1990). It is not clear, however, what type of cell is responsible for IFN-α production in people infected with HIV-1 because, in vitro, HIV-1 infection of PBL does not result in the induction of IFN gene expression. PBMC isolated from individuals infected with HIV-1 or from AIDS patients has impaired IFN production upon stimulation with double-stranded RNA, NDV or HSV-1 (Fitzgerald-Bocarsky et al. 1989). This impairment in IFN production seems to occur at the transcriptional level (Gendelman et al. 1990).

In contrast, HIV-1 infection in vitro seems to induce cytokine expression. Thus, stimulation of HIV-1-infected monocytes with bacterial antigens from *Pneumocystis carinii* or *Mycobacterium avium* results in enhanced expression of TNF-α, IL-1, IL-6 and IL-8 mRNAs, compared to those present in stimulated but uninfected controls (Newman et al. 1993; Kandil et al. 1994). Both enhanced and unaltered cytokine expression have, however, been reported in HIV-1-infected monocytes stimulated with LPS, and no difference in cytokine production between HIV-1-infected and uninfected monocytes has been observed after stimulation with endotoxin or double-stranded RNA (Gendelman et al. 1990; Molina et al. 1990). A large variability in reported results suggests that inducible expression of cytokine genes may depend both on genetic determinants and on the nature of the inducer.

The molecular mechanism by which HIV-1 infection alters spontaneous and inducible cytokine gene expression is not clear. However, as most of the cytokines (whose expression is up-regulated by HIV-1 infection) contain an NF-κB enhancer in their promoter and NF-κB-specific binding is essential for transcription activation, it is likely that the binding of the HIV-1 or gp120 to the CD4 receptor induces change in the signaling pathways, such as those leading to the activation of NF-κB heterodimers, that alter both the constitutive and the inducible expression of the cytokine genes.

Effect of cytokines on HIV-1 replication

Transcription of HIV-1 is controlled by cellular and viral transactivators that bind to regulatory sequences present

both in the long terminal repeat (LTR) of HIV-1 provirus and in the untranslated leader sequence of viral RNAs. Activation of viral transcription occurs upon binding of virally encoded tat protein to the tat-binding region present in all viral mRNAs (Rosen et al. 1985; Cullen and Greene 1989). In contrast, DNA elements present in the HIV-1 LTR, such as NF-κB enhancer (Nabel and Baltimore 1987), play a major role in the activation of the promoter by cellular and extracellular factors. Additional regulation of the inducible response is mediated through specific interaction between nuclear transactivators and the AP-1, NFAT, LBP-1, HLP-1, and TCF-1 DNA-binding sequences (Jones et al. 1988).

Many inflammatory cytokines stimulate HIV-1 transcription from the LTR and affect HIV-1 replication (Butera 1993; Poli and Fauci 1993). This observation is of biological importance, because cytokines are released during the immune response to HIV-1 infection and increased cytokine expression can be detected in lymph nodes in the vicinity of the focus of infection (Emille et al. 1991). The local environment in the infected lymph nodes allows for extensive interactions between activated B cells and T cells, resulting in the production of a variety of cytokines secreted in both an autocrine and a paracrine fashion. The profile of cytokines induced at the site of infection can then not only determine the nature of the immune response (cellular immunity mediated by CTL response versus antibody response) but also directly affects HIV-1 replication and thus positively or negatively enhances the progression of disease.

Cytokine-mediated up-regulation of HIV-1 replication

Of the stimulatory cytokines, TNF-α probably has the most significant effect on HIV-1 replication and a direct role in the pathogenicity of HIV-1 infection has been attributed to it. In vitro, TNF-α can up-regulate the transcriptional activity of HIV-1 LTR and the effect is mediated by the induction of NF-κB binding in the nucleus (Duh et al. 1989; Osborn et al. 1989). It has been shown that the TNF-α-mediated signal transduction pathway begins with the binding of TNF-α to one of the membrane receptors TNF-Rβ (55 kDa) and proceeds through sphingomyelinase and ceramide (Schutze et al. 1992). The TNF-α-mediated activation is not limited to the HIV-1 LTR. TNF-α can also effectively induce the expression of poorly expressed (latent) HIV-1 provirus in both T cells and monocytes. An interesting feature of TNF-α activation from the point of view of HIV-1 replication is that it is independent of transactivation mediated by the virus-encoded transactuator, tat. TNF-α can effectively rescue transcription and viral replication of a mutant HIV-1 provirus in which the tat region is deleted and therefore transcriptionally inactive (Popik and Pitha 1993). These results point to the existence of an alternative pathway in HIV-1 transcription regulation that is independent of tat. Because elevated levels of TNF-α can be detected in the serum in the later stages of HIV-1 infection, it is assumed that TNF-α is one of the factors that contribute to the progression of the disease and to some of the clinical signs, such as AIDS-associated weight loss (Serwadda et al. 1985). The ability of TNF-α to activate HIV-1 replication in a tat-independent manner has important implications for the antiviral strategies aimed at eliminating tat transactivation. Effective inhibition of HIV-1 replication requires both tat and NF-κB inhibition, and, in the presence of TNF-α, the drug RO5 that blocks tat transactivation is not effective (Popik and Pitha 1994). Thus, the presence of TNF-α in the serum and the ability of TNF-α to transactivate HIV-1 replication in a tat-independent fashion may be one of the reasons why the drug RO5 was ineffective in clinical trials.

Several other cytokines up-regulate HIV-1 transcription and HIV-1 provirus in vitro. In vitro, IL-1 stimulates transcription of a latent HIV-1 provirus in both T cells and monocyte lines (Poli et al. 1994). The induction was associated with the stimulation of NF-κB activities. IL-3 and the proteins of the colony stimulating factor (CSF) family, GM-CSF and M-CSF, up-regulate HIV-1 replication in primary macrophages and in monocyte and myeloid cell lines (Gendelman et al. 1990). It is interesting that CSF-mediated stimulation does not seem to be mediated entirely through NF-κB binding, as the region upstream of the NF-κB enhancer is also required for activation (Zack et al. 1990). IL-6 is another cytokine that has been implicated in the upregulation of HIV-1 replication (Poli et al. 1994). In contrast to the other cytokines, IL-6-mediated enhancement does not seem to take place at the transcriptional level, but occurs at the post-transcriptional level. The exact mechanism of this enhancement is not known. Of importance from a biological point of view is the synergy between IL-6 and TNF-α or IL-1 which leads to a significant enhancement of HIV-1 replication (Poli et al. 1990, 1994).

Cytokine-mediated down-regulation of HIV-1 infection

Recent data indicate that progression to AIDS is accompanied by a shift from a Th1 cytokine response and production of IL-2 and IFN-γ to a Th2 cytokine response, with production of IL-4, IL-6, and IL-10. In vivo, production of IFN-γ during the Th1 response may play a role in the down-regulation of HIV-1 infection. Although in vitro HIV-1 infection in macrophages does not induce IFN-α or IFN-β production, IFN-α can be detected in serum during the later stages of HIV-1 infection. The biological role in vivo of this IFN is not known, but IFN-α, IFN-β, and IFN-γ can effectively inhibit HIV-1 replication in vitro.

In vitro, IFNs inhibit HIV-1 replication both in primary cells and in established T cells and monocytic cell lines (Yamamoto et al. 1986; Kornbluth et al. 1989; Poli et al. 1989; Gendelman et al. 1990). In a single cycle infection in T cells (Shirazi and Pitha 1992) or in IFN-producing cells (Bednarik et al. 1989), IFN inhibits early steps in HIV-1 replication and HIV-1 transcripts cannot be detected in these cells (Shirazi and Pitha 1993). Furthermore, in primary macrophages, Type 1 IFNs decrease the levels of integrated provirus (Kornbluth et al. 1990). Hence, in multiple infection cycles or in chronic infection, IFN inhibited HIV-1 replication at the post-translational level and decreased the levels of virus released into the culture medium, but did not substantially affect the synthesis of viral RNA and proteins in infected cells. The mechanism by which IFN inhibits HIV-1 replication at the preintegrational step is not clear. Inhibition of the early replication steps has been observed in cells constitutively producing low levels of IFN-β, and it has been suggested that inhibition occurs at the level of viral uptake.

IFN also inhibits the activation of HIV-1 provirus by external stimuli in vitro. Poli et al. (1989) have shown that TNF-α-mediated stimulation of HIV-1 provirus is inhibited by IFN-α, and it has been suggested that the IFN-mediated block is at the level of virus maturation and assembly. Activation of a *tat*-defective provirus by 12-*O*-tetradecanylphorbol 13-acetate (TPA) or by HSV-1 is also inhibited in the presence of IFN. However, the inability of these inducers to activate HIV-1 provirus in the presence of IFN occurs at the transcriptional level, and is associated with the alteration of NF-κB-specific binding (Popik and Pitha 1991, 1992).

Several studies have shown that, although HIV-1 infection does not induce IFN type I synthesis in vitro, it can modulate the levels of at least two dsRNA-dependent enzymes, 2′,5′-OAS and RNaseL, and induce expression of Mx protein. It has also been shown that the activation of PKR by tat-binding region (Edery et al. 1989) inhibits the translation of HIV-1 mRNAs and that inhibition of protein synthesis correlates with phosphorylation of eF-2. Yet none of these IFN-induced proteins seems to play a significant role in the IFN-mediated inhibition of HIV-1 replication. Neither small nor large 2′,5′-OAS can be detected in HIV-1-infected cells (Popik and Pitha, unpublished). Productive HIV-1 infection leads to a decrease, not an increase, in cellular PKR activity. It has been suggested that the binding of the cellular protein tat region binding protein (TRBP) to the tat-binding region interferes with recognition of the dsRNA structure and prevents induction of PKR (Park et al. 1994) in HIV-1-infected cells. Together, these results indicate that IFN can inhibit many steps of the HIV-1 replication cycle with differing efficiency and they suggest that, in vivo, IFN may have a broad spectrum of action (Figure 2).

Cytokines with both stimulatory and inhibitory effects on HIV-1 replication

The wide range of biological properties of certain cytokines is often manifested by their bifunctional effects. This is also true of their effects on HIV-1 replication. TGF-β pretreatment can stimulate HIV-1 replication in primary T cells and in myeloid and monocytic cell lines (Lazdins et al. 1991; Poli et al. 1991). However, when TGF-β is applied to infected cultures, it inhibits PMA, TNF, and IL-6-mediated stimulation of HIV-1 replication (Poli et al. 1991). IL-4 is another cytokine with a bifunctional effect on HIV-1 replication: it can either induce or inhibit HIV-1 replication in myeloid cells. In undifferentiated monocytes, IL-4 stimulates HIV-1 replication, as well as the proliferation of the cells (Kazazi et al. 1992; Foli et al. 1995) whereas, in differentiated macrophages, IL-4 suppresses HIV-1 replication (Novak et al. 1990). In T cells, however, IL-4 does not affect HIV transcription. This indicates that differences in host cells and types of infection, as well as the timing of exposure to cytokines, may determine the outcome of the cytokine effects.

Herpesvirus infections

Herpesviruses selectively regulate proinflammatory cytokine synthesis. Human herpesvirus-6 infection induces high levels of IL-1β and TNF-β in wildtype cultures, but inhibits the induction of IL-6. In the same cells, EBV inhibits TNF-α secretion (Gosselin et al. 1992). The pattern of cytokine expression during herpes simplex virus-induced keratitis (HSK) has been well studied in the mouse and human cornea. HSV-1 infection in murine keratinocytes induces transient expression of TNF-α, IL-6, and IL-1, a cytokine profile that is characteristic of a transient inflammatory response (Sprecher and Becker 1992). Exogenous IL-10, a cytokine with inflammatory suppressive activity, also significantly decreases IL-6 levels in HSV-1-infected murine cornea and sharply reduces the incidence of blindness secondary to the HSV-1-induced inflammatory response, even though IL-1α levels are not decreased (Tumpey et al. 1994). At low concentrations, IFN-γ and TNF-α induce a synergistic antiviral effect against HSV-1 in human corneal cells (Chen et al. 1994). Cells isolated from eyes in the active phase of HSK have been found to be of the $CD4^+$ Th1 subset, secreting IL-2, IFN-γ, and TNF-α, but not IL-4 or IL-10 (Niemialtowski and Rouse 1992). Treatment with monoclonal antibodies specific for IFN-γ or IL-2 reduces the severity of HSV-1-induced corneal inflammation in mice, and inhibition of IFN-γ production by UV-irradiation enhances IL-4 production, as well as zosteriform skin lesions (Hendricks et al. 1992; Yasumoto et al. 1994). These findings indicate that Th1 and Th2 responses define the pathogenicity of HSV-1 in

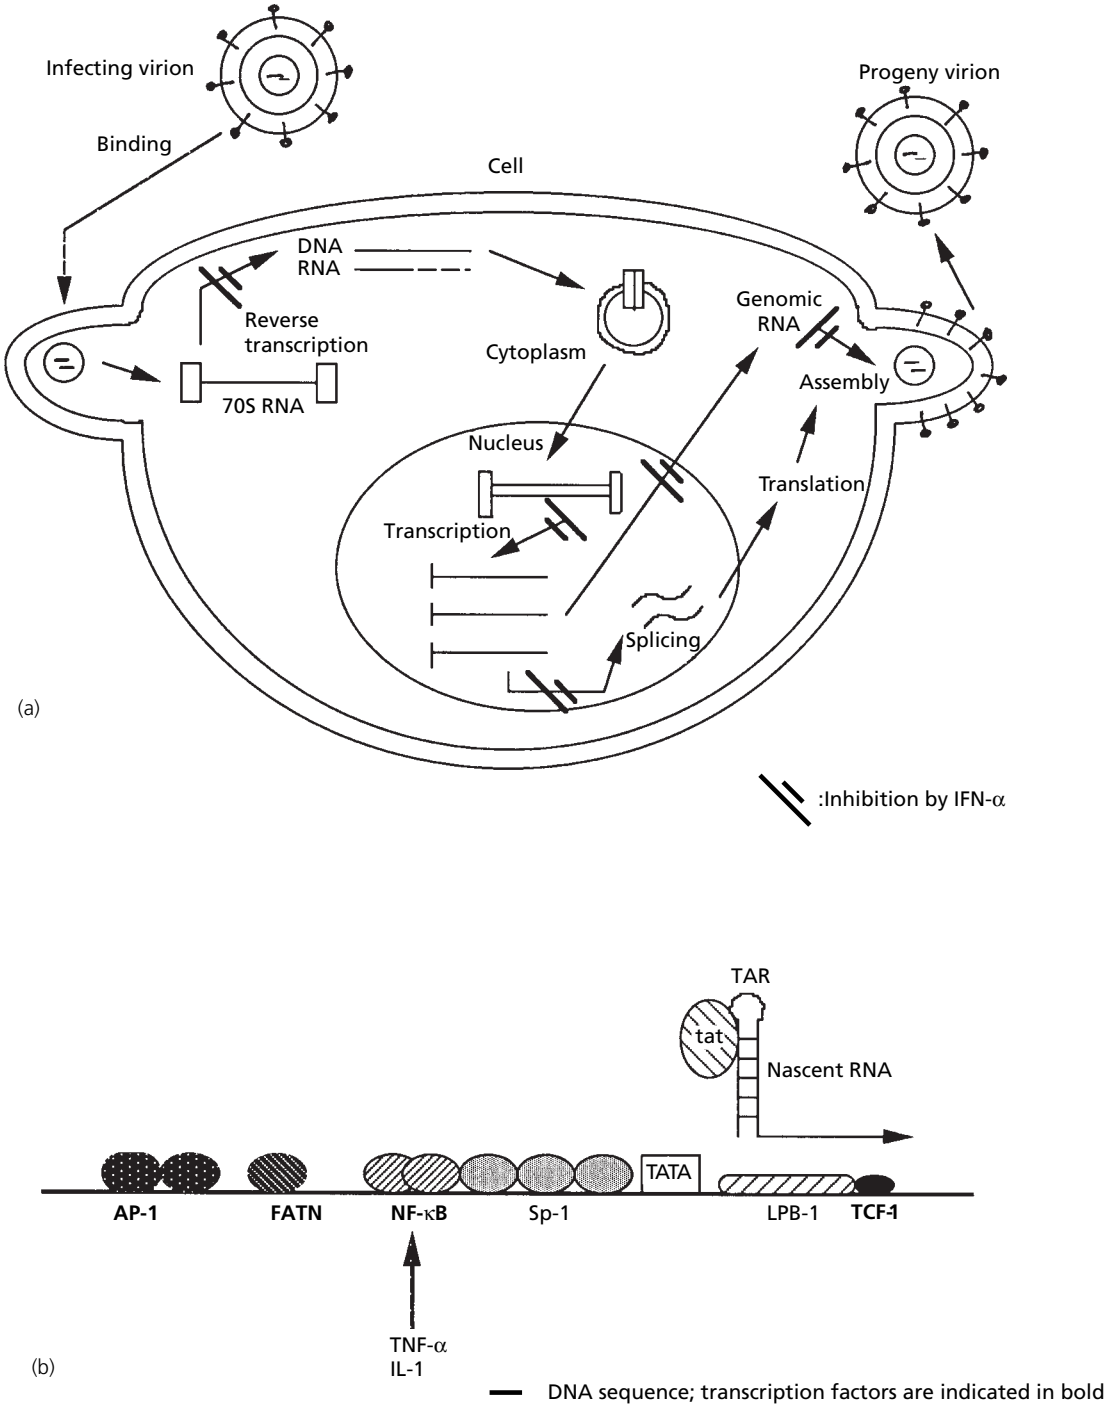

Figure 2 (a) *IFN-α inhibition of the HIV-1 life cycle.* **(b)** *Cytokine activation of* HIV *long terminal repeats.*

the cornea and the skin. HSV-1 and -2 activate macrophages and induce IFN-α/β production, which synergizes with TNF-α in an autocrine manner to protect macrophages from herpetic infection (Ellerman-Eriksen et al. 1994).

EBV infection is associated with acute, self-limiting, infectious mononucleosis, chronic infectious mononucleosis, and lymphoproliferative disease (LPD). In all acute forms of EBV infection, IFN-γ, TNF-α, IL-2, and IL-6 are elevated (Linde et al. 1992). EBV-associated LPDs are a common complication of primary immunodeficiency and are associated with elevated serum levels of IL-4 and, to a lesser extent, IL-5, IL-10, and IFN-γ (Mathur et al. 1994). Cyclosporin A, used in immunosuppressive therapy, increases EBV-associated lymphoproliferative disorders by inducing

IL-6 expression in T cells and by increasing the number of EBV-immortalized B cells expressing viral lytic antigens. Exposure to EBV stimulates IL-6 expression in B cells and in monocytes (Tanner and Menezes 1994).

EBV-infected B cells express IL-10 and B-cell regulatory factor (BCRF) 1, the viral homologue of IL-10, and expression of both viral and cellular cytokines is maintained during transformation. Inhibition of viral IL-10 (vIL-10) expression with antisense oligonucleotides at the time of viral challenge prevents EBV B-cell transformation. Conversely, transformation is rescued by exogenous cellular IL-10. These observations indicate that EBV-encoded *IL-10* is a latency gene involved in B cell transformation (Miyazaki et al. 1993). EBV has been implicated in the etiology of Sjögren's syndrome, a disease characterized by lymphocytic infiltration, squamous cell metaplasia and a decrease in goblet cell numbers in the conjunctival epithelium of the eye. Although the marker for latent EBV infection, EBNA-1 or EBV IL-10 is not expressed at a higher frequency than in the normal eye, HLA-DR, ICAM-1, and IL-6 expression is significantly increased in Sjögren's syndrome (Jones et al. 1994).

Infections with hepatitis viruses

Hepatitis virus clearance and persistence hinge upon the intricate, and as yet not fully understood, modulation of virus-induced cytokines. Monocytic production of IL-6, the mediator of acute-phase protein synthesis in hepatocytes, is decreased in chronic HBV infection, whereas it is normal in chronic hepatitis C virus (HCV) and in acute hepatitis A virus (HAV), HBV and HCV infections. Exacerbation of chronic HBV induces expression of IL-6 and TNF-α which correlates with an increase in HBV DNA levels in serum (Kakumu et al. 1991; Sheran et al. 1991). Moreover, IL-6 contains recognition sites for the segment of the HBV envelope protein through which the virus binds to cell surfaces (Neurath et al. 1992).

HBV is not cytopathic, but it evokes a strong lymphomononuclear inflammatory response in the liver during acute and chronic infections. Transgenic mice whose hepatocytes do not secrete HBV, but retain the antigen in the endoplasmic reticulum, are highly susceptible to liver damage induced by bacterial lipopolysaccharide, a potent inducer of inflammatory cytokines. The effect seems to be mediated by both IFN-γ and TNF-α. Hepatocellular injury and induction of inflammatory cytokines coincide with a reduction in HBV steady-state mRNA content (Gilles et al. 1992). TNF-α induces two other proinflammatory cytokines, IL-8 and IL-6, in patients with chronic HBV. Inflammatory cytokines appear to down-regulate HBV expression by both TNF-α-dependent and TNF-α-independent pathways. Administration of exogenous recombinant TNF-α, IL-2, IFN-α, and IFN-β has been shown to reduce steady-state levels of HBV RNA in transgenic mice. TNF-α antibodies block the effect of TNF-α and IL-2, but not that of IFNs. Administration of exogenous IFN-γ, IL-1, IL-3, IL-6, or TNF-α has no effect on the HBV RNA levels (Guidotti et al. 1994). De-regulation of the inflammatory cascade can have disastrous effects, as illustrated by fulminant hepatic failure, characterized by a striking elevation of IL-6, TNF-α, IL-1Rα, and IL-1β levels (Sekiyama et al. 1994). IFN-γ and HBV X protein increase the rate of transcription of intercellular adhesion molecule 1 (ICAM-1), a molecule critically important to adhesion-dependent leukocyte functions, such as antigen presentation and target cell lysis (Hu et al. 1992). IFN-γ initially also activates HBV-specific class I restricted CTL, suppressing expression of the HBV gene.

Chronic hepatitis B, C, or D may lead to cirrhosis, hepatocellular failure or hepatocellular carcinoma. IFN-α has recently become the treatment of choice for chronic hepatitis, because HBV and HCV infections respond well to treatment with it. Sustained loss of HBV DNA and HBV nucleocapsid and surface antigens leads to the restoration of normal liver function. However, the relatively high prevalence of resistance of HBV to IFN is of concern. It was shown that the terminal domain of HBV polymerase is responsible for the resistance of the virus to IFN-α and IFN-γ. Individuals infected with several HCV quasi species seem to be less responsive to IFN therapy than are those with a single major species (Gutterman 1994; Dusheiko 1995).

CYTOKINE RESPONSES TO VIRAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

There is increasing evidence that local cytokine production induced as a response to viral infection of cells of the CNS or infiltrating lymphoid cells plays a crucial role in the pathogenicity and outcome of viral infection in this location (Benveniste 1992).

Local synthesis of TNF-α within the CNS seems to be especially damaging. TNF-α damages glial cells and has a direct toxic effect on neurons. In vitro, TNF-α induces demyelination of oligodendrocytes, whereas the closely related TNF-β kills oligodendrocytes by inducing apoptosis. Production of both TNF-α and TNF-β in the CNS results in the death of myelin-producing oligodendrocytes. TNF-α can also act indirectly by stimulating microglia and astrocytes to produce nitric oxide and the neurotoxic metabolites of arachidonic acid (Benveniste 1995). TNF-α also stimulates synthesis of other cytokines such as GM-CSF, G-CSF, and M-CSF, which enhance inflammatory responses as well as the synthesis of IL-6 (Doherty et al. 1989; Moskophidis et al. 1991; Campbell et al. 1994). IL-6 enhances inflammation

in the CNS, as well as stimulating the proliferation of B cells and their differentiation into antibody-producing cells.

The local immune responses in the CNS and the outcome of the infection are affected by the cytokines induced in situ, whether directly in infected cells (Sebire et al. 1993; Wesselingh et al. 1994), as a response to viral infection (e.g. IFNs, TNF-α or IL-6 in astrocytes or microglia) or by infiltrating T cells and macrophages during local inflammation (Shankar et al. 1992; Gillespie et al. 1993).

It is interesting that the profile of cytokines synthesized in the CNS seems to be determined by the type of infecting virus rather than by the type of host cells. Thus, infection of neurons with LCMV leads to synthesis of TNF-α, IL-1, IL-6, and IFN-γ, generating a strong CTL response (Campbell et al. 1994). The strong Th1 cytokine response and induction of cytotoxic T cells leads ultimately to death, whereas viral replication alone is regulated by the presence of IFNs. The association of LCMV pathogenicity with the immune response provided the first clear evidence that viral pathogenicity may be mediated by the immune response of the host (Rowe 1954). In contrast, the infection of neurons with the Sindbis virus (an alphavirus closely related to Western equine encephalitis virus), which causes acute encephalomyelitis in mice, results in generation of the Th2 cytokine response (Wesselingh et al. 1994). Increases in mRNAs and IL-1, IL-4, IL-6, IL-10, and TNF-α proteins have been observed during the early stages of acute infection in mice, followed by the appearance of antiviral antibodies and clearance of virus from the CNS (Tyor et al. 1989; Levine et al. 1991). Although it has been suggested that the CNS may provide an environment that favors B-cell antibody response, it is difficult at present to generalize this finding. Thus, recovery from acute HSV infection depends on a T-cell response, whereby the MHC class I-restricted $CD8^+$ cytotoxic T lymphocytes control HSV infection in the brain (Schmidt and Rouse 1992; Nash and Cambouropoulos 1993). Secretion of IFN-γ from activated T cells is critical for clearing of herpes virus infection (Raniero et al. 1990; Lucin et al. 1992). Recently, it has been shown that the T cell inflammatory response and production of IFN-γ persist in trigeminal ganglia long after HSV-1 has established the latent phase of infection (Cantin et al. 1995). This observation may indicate that the prolonged production of IFN-γ and possibly also of other cytokines (e.g. TNF-α) (Schmidt and Rouse 1992) may block or suppress HSV-1 replication after reactivation from latency (Cunningham and Merigan 1983; Torseth and Merigan 1986).

De-regulated local production of cytokines in the brain has also been observed in patients with AIDS dementia complex (ADC), which afflicts 30–50 percent of all people infected with HIV-1 (Johnson et al. 1988). In the CNS, HIV-1 can be found primarily in infiltrating monocytes and macrophages, as well as in resident microglia (Koenig et al. 1986; Wiley et al. 1986), but there is evidence for major damage to neurons (Ketzler et al. 1990). There is no explanation at present for the cause of this extensive neurological impairment. It has been suggested that cytokines produced in macrophages and glial cells in response to HIV-1 infection (Gelbard et al. 1994) may either directly damage the neurons or alter the function of astrocytes and, consequently, neuronal function (Benveniste 1992, 1995).

Analysis of the cerebrospinal fluid from ADC patients has shown elevated levels of IL-1, TNF-α, IL-6, and neopterin, an indicator of the presence of IFN-γ (Grimaldi et al. 1991). With the exception of IFN-γ, all these substances are the products of activated macrophages and microglia. IFN-γ is most likely to be produced by infiltrating $CD8^+$ cells (Tyor et al. 1992). The expression of cytokine mRNA in the brain has been analyzed (Wesselingh et al. 1993). The results reveal a strong association between increased levels of TNF-α mRNA and ADC. As discussed above, TNF-α induces many abnormalities in the CNS and so its overproduction may be one of the causes of the neuron dysfunction in ADC. It is interesting that an increased number of TNF-α-producing cells was also observed in patients with other neurological disease, such as multiple sclerosis (Benveniste 1995). These data suggest that TNF-α may play a major role in inflammatory disorders of the CNS.

DIRECTED CYTOKINE EXPRESSION WITH RECOMBINANT VIRUSES

The role of individual cytokines in response to viral infection has been studied by using recombinant cytokines administered systematically. This approach does not mimic well conditions in vivo, in which cytokines are acting locally and presumably in much higher concentrations (Biron et al. 1990). Results from experiments with transgenic animals expressing IL-2 (Ishida et al. 1989), IL-4 (Tepper et al. 1990), IL-5 (Tominaga et al. 1991), or GM-CSF (Lang et al. 1987) have often been difficult to interpret, because of the widely spread expression. More clear-cut results have been obtained with experiments in which animals with a homozygous deletion of a given cytokine or its receptor are used (e.g. IFN-γR nu/nu mice (Huang et al. 1993), IL-6 nu/nu mice) or when production of cytokines is suppressed by monoclonal antibodies (Leist et al. 1989).

Recently, a new technique has been used, whereby a cytokine gene inserted in a nonessential part of a recombinant virus is able to target cytokine production directly to the focus of infection. This makes it possible to determine the effect of local cytokine production on viral replication and the immunological consequences of cytokine overproduction. The most common type of virus for cytokine delivery has been vaccinia virus (Ramshaw

et al. 1992), although HSV-1 (Mester et al. 1995) and mouse cytomegalovirus (Burnes, personal communication, 1995) have also been used.

Vaccinia virus is a complex DNA virus that replicates in the cytoplasm. Foreign DNA can easily be inserted into the virus under the control of a viral promoter (Davidson and Moss 1989), and foreign proteins are processed and transported with fidelity (Moss and Flexner 1987). Furthermore, a large region of this virus DNA genome is not essential for replication. Insertion of the *IL-2* gene into vaccinia virus enhances neither T cell-mediated immunity nor the immune response, but it decreases the virulence of the virus and enables immune-suppressed mice to resolve infection (Ramshaw et al. 1992). Enhancement of NK cell cytotoxic activity is an important factor in the clearance of infection in nude mice, and it has been found that IFN-γ plays an essential role in IL-2-mediated recovery. Since no host response was demonstrated that explained the rapid clearance of IFN-γ-expressing virus, these authors concluded that the observed inhibition in viral replication is caused by the direct antiviral effect of IFN. Similarly, the recombinant virus expressing TNF-α was rapidly cleared without any detectable involvement of the host immune system. Furthermore, local production of TNF-α was not toxic and no pathogenicity induced by TNF-α could be detected. Thus, TNF-α, like IFN-γ, seems to inhibit viral replication by the direct antiviral effect (Sambhi et al. 1991). These results indicate that overproduction of Th1 cytokines inhibits viral replication. Inhibition of viral replication is localized and limited to the recombinant virus and does not affect the coinoculated control virus (Ramshaw et al. 1992).

To determine the effect of Th2 cytokines on the course of viral infection, recombinant viruses expressing Th2 cytokines have been constructed. In normal mice, recombinant virus encoding IL-4 replicates more efficiently than control virus, whereas expression of IL-5 or IL-6 has no apparent antiviral effect. However, vectors encoding IL-5 and IL-6 significantly increase terminal differentiation of IgA-committed B cells and mucosal IgA antibody response in vivo (Ramsay and Kohonen-Corish 1993; Ramsay et al. 1994). Expression of IL-6 augments both the primary systemic antibody and the mucosal antibody responses. In contrast, expression of IFN-γ significantly inhibits antibody responses without affecting the general cell-mediated immune response (Leong et al. 1994). Furthermore, the vectors expressing IL-6 are able to reconstitute the IgA and IgG responses in IL-6-deficient mice (Ramsay et al. 1994). These results indicate that IL-6 plays a critical role in the induction of mucosal immunity.

Herpes simplex virus type 1 (HSV-1) has also been used for targeted delivery of cytokine genes. Weir and Elkins (1993) inserted a human IFN A gene into a replication-incompetent herpesvirus and showed that IFN expressed in infected monocytes is able to inhibit HIV-1 replication. Murine IFN A has been inserted in both replication-competent and incompetent HSV-1. HSV-1-derived IFN A gene expression did not inhibit HSV-1 replication in vitro. However, preinfection of the cells with the nonreplicating HSV–IFN vector provided complete protection against a subsequent viral challenge (Mester et al. 1995). Replication-defective vectors derived from HSV-1 have also been used for delivering genes to neurons (Fink et al. 1992), suggesting their usefulness for analyzing cytokine effects within the nervous system. In summary, these approaches suggest a novel and highly effective approach to the study of local cytokine effects in viral infections and to the effectiveness of virus-derived vectors in vaccine development and cytokine gene therapy.

CONCLUSION

It is evident that viral infection induces a complex host response mediated by the induction of genes encoding various cytokines and lymphokines, as well as stress proteins. This response can be induced directly in the infected cells or indirectly in cells of lymphoid origin tethered to the focus of infection during the immune response. The primary function of these cytokines is either to inhibit viral replication or to activate the cells mediating the cellular and humoral immune responses. However, inflammatory cytokines, produced during the immune response, are not always beneficial to the host and can contribute to the pathogenicity and side-effects of viral infections. The detrimental effect of cytokines can be most clearly demonstrated in conditions in which infection is localized to a specific organ or system such as the CNS. Then, production of even relatively low levels of cytokines, such as TNF-α, can have profoundly toxic effects and result in the death of neurons or the dysfunction of oligodendrocytes.

Several viruses have developed ways to eliminate or overcome the effect of cytokines. This again demonstrates the great plasticity of some viral genomes and their ability to adapt. Thus, HIV-1 has modified its regulatory region to resemble the promoter of some of the inflammatory cytokines, and can therefore use several of the inflammatory cytokines to stimulate its own replication. Other viruses, such as the poxviruses, carry several genes that encode soluble cytokine receptors. Others, such as adenovirus, have developed a specific mechanism that can allow them to inhibit the effects of cytokines. Some of the HIV-1-encoded accessory proteins may carry similar functions. Expression of viral genes that inhibit cytokine induction and function seems to be essential for the replication of many of these viruses in vivo, because the replication and pathogenicity of mutants with 'mimicry' functions deleted are usually considerably diminished. One of the main objects of future research should, therefore, be to characterize these cytokine-inhibiting viral functions. This

would help not only to understand the role that a given cytokine plays in a particular viral infection but also to generate attenuated, nonpathogenic viruses that could be used for vaccine development. However, the real challenge will be to use the mechanisms that viruses have developed to avoid the immune response as selective tools to eliminate viral infections.

INTRODUCTION: AN INTIMATE RELATIONSHIP BETWEEN VIRUSES AND THEIR HOSTS

Viruses depend on the cell for replication and production of new virus particles, and thus viruses have established a complex interaction with the cellular machinery for nucleic acid replication and protein synthesis, and have 'learned' how to take advantage of cellular compartments to generate virus particles. The viral replication cycle and morphogenesis of virus particles can be observed in vitro in cell culture. However, in real life, viruses replicate in an animal host that is well prepared with a variety of defense mechanisms to prevent viral infection. In turn, viruses have evolved many different strategies to counteract host defenses.

The immune evasion strategies used by different virus families are related to the 'lifestyle' of the virus, which depends on the nature and replication of their genetic material, cell tropism, mechanism of transmission, and ability to persist in the infected host. Some viruses such as human immunodeficiency virus (HIV) infect immune cells and may cause immunosuppression. RNA viruses take advantage of the high mutation rate of the RNA polymerases to generate variants that escape recognition by the host immune system. Herpesviruses establish latency, a viral stage that maintains the viral genome with minimal expression of viral proteins, avoiding recognition by the host immune system and allowing viral persistence for the life of the host. In this case, intermittent phases of reactivation generate newly synthesized virus particles to ensure transmission to other individuals and virus persistence in the host population. Recent investigations during the last few years have shown that viruses not only hide to avoid immune recognition but they take a very active role to interfere with specific molecular mechanisms of immunity. Large DNA viruses, such as poxviruses and herpesviruses, may accommodate between 100 and 200 genes in their genomes and have the capacity to code for a large number of proteins that interfere with the immune antiviral response.

Viral strategies of immune evasion block the development of innate (nonspecific) or adaptive (antigen-specific) immune responses. The innate response constitutes the first line of immune defense since it does not require previous encounters with the viral agent, and is rapidly activated during the first hours after infection. Innate responses include interferons (IFN), the complement system or natural killer (NK) cells. The adaptive immune response consists of antibodies and cytotoxic T cells (CTL) which are directed against specific antigens encoded by the viral invaders. This response requires days or even weeks to develop and induces immunological memory, so that the host will respond more

rapidly and efficiently to viruses that have been experienced previously. The inflammatory response illustrates how innate responses may favor specific immune responses. As a result of viral infection and tissue damage, the inflammatory response is triggered which is characterized by an increased permeability of blood vessels and the production of soluble mediators such as cytokines and chemokines which induce the migration of immune cells into areas of infection. The end result is a massive infiltration of cells and soluble factors that protect the host from viral infection and trigger antigen-specific cellular and humoral responses that will offer further protection mechanisms.

The activation of the immune response requires the cooperation of T helper (Th) lymphocytes which differentiate into Th1 and Th2 cells that produce specific sets of cytokines. Th1 cells produce cytokines such as interleukin (IL)-2 and interferon (IFN)-γ that promote cellular pro-inflammatory responses associated with the maturation of macrophages and CTLs. Other cytokines such as IL-12 play an important role by inducing Th1 and NK cells to produce IFN-γ. By contrast, Th2 cells promote the humoral response inducing the differentiation of B cells to produce antibodies. In addition, Th2 cells produce IL-4 and IL-10 which may reduce cellular inflammatory responses. Whereas cellular immune responses are thought to play a critical role in viral elimination once viral infection has been established, the antibody response plays an important role in preventing the early stages of infection.

We have just started to understand the complex interaction of viruses with their hosts and how viruses achieve an equilibrium leading to the survival of both virus and host. Viruses are fully dependent on the host for their replication and production of progeny virus, and thus they should avoid high virulence that may lead to extermination of the host. Much of the pathology associated with viral diseases may be the result of an unbalanced virus–host interaction, and in some cases it represents uncontrolled attempts of the immune system to destroy the virus that lead to damage of the host. It has become clear that a more profound knowledge of the interaction of viruses with their host will help us to understand the molecular mechanisms of viral pathogenesis.

The study of the interaction of viruses with the host immune system is a research area that has expanded enormously in recent years and it is not possible to cover all aspects in depth in a chapter. Here I provide a general view of the different strategies used by viruses to evade the host immune response. Basic concepts of viral immune evasion are discussed and illustrated with representative examples. More information can be found in review articles (Alcami and Koszinowski 2000; Johnson and Hill 1998; Katze et al. 2002; Seet et al. 2003; Tortorella et al. 2000).

INHIBITION OF HUMORAL IMMUNITY

Genetic variability

The production of antibodies specific to viral antigens that neutralize virus particles is an important mechanism to prevent viral infection. One of the first mechanisms of immune evasion identified in viruses was the accumulation of mutations that translate into antigenic variability, a mechanism that has special relevance in viruses with RNA genomes (Flint et al. 2000). In contrast to DNA polymerases, RNA polymerases have low fidelity and introduce a high rate of mutations as the genetic material is copied. As a consequence, viral RNA genomes consist of a collection of RNA species (quasi species) carrying point mutations. These mutations translate into viral epitopes that are recognized with lower affinity by antibodies that neutralize the infectivity of the viral particles. An example of this strategy is found in rhinoviruses, which exist in the human population in the form of 160 serotypes. Neutralizing antibodies raised after the infection with one particular serotype do not protect from infection by other viral serotypes. Genetic variability may also generate variant peptide sequences that have lost the ability to bind to major histocompatibility complex (MHC) molecules, thus evading recognition by the cellular immune system as well.

Influenza virus is one of the best examples to illustrate genetic variability as a mechanism to escape immune recognition (Flint et al. 2000). The genome of influenza virus consists of eight RNA fragments encoding different proteins, including the virion surface proteins known as hemaglutinin (HA) and neuraminidase (NA). Coinfection of the same host with influenza viruses bearing different subtypes of HA and NA may generate virus particles containing new combinations of genomic fragments. This results in a sudden change of antigenic properties, known as antigenic shift, that facilitates the immediate evasion of neutralizing humoral responses in the majority of the population. This phenomenon may lead to pandemics such as that of 1918 in which more than 20 million people died. At the same time, influenza virus accumulates point mutations continuously due to the low fidelity of its RNA polymerase, a phenomenon known as antigenic drift. These limited changes are responsible for the flu epidemics of each season.

Fc receptors

Some viruses encode receptors for the Fc domain of immunoglobulin G (IgG) to evade the action of antibodies (Johnson and Hill 1998) (Figure 1). The glycoproteins gE and gI from herpes simplex virus (HSV) form a heterodimeric complex that functions as an Fc receptor. It has been proposed that gE–gI interacts with antibodies

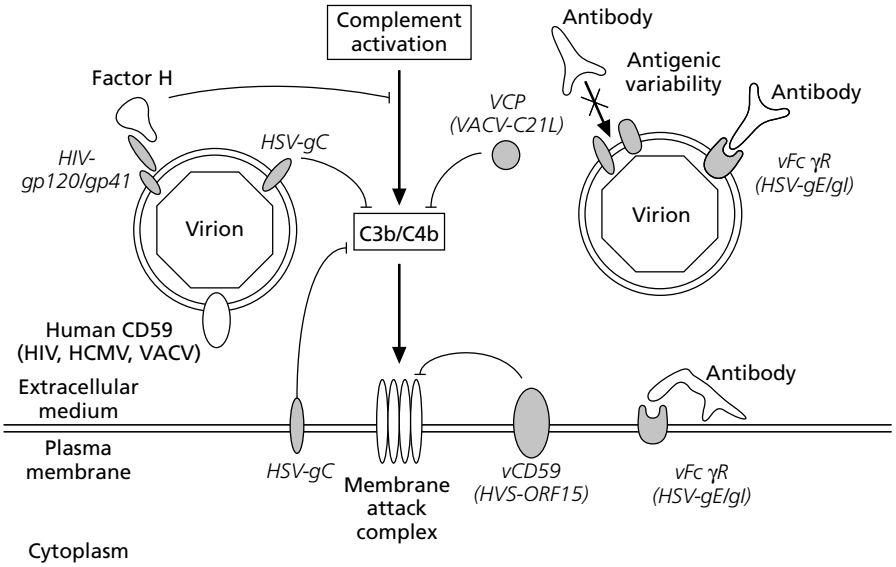

Figure 1 *Viral mechanisms to evade the complement and antibody responses*

that recognize specific HSV antigens and inhibit complement-mediated antibody neutralization and antibody-dependent cellular cytotoxicity by cells carrying Fc receptors (Frank and Friedman 1989; Lehner et al. 1975). The spike protein of the coronaviruses mouse hepatitis virus, bovine coronavirus, and transmissible gastroenteritis virus display Fc receptor activity (Oleszak et al. 1993).

Complement system

The complement system constitutes one of the major defense systems against pathogens. Viral antigens or antigen–antibody complexes may activate the complement cascade, a complex family of proteins that are sequentially activated and culminates with the formation of a membrane attack complex leading to the destruction of infected cells or the envelope of virus particles in those viruses with an outer lipid membrane.

Herpesviruses and poxviruses encode proteins with amino acid sequence motifs found in complement regulatory proteins and bind critical factors in the complement activation pathways, such as C3b and C4b, and inhibit their activity (Favoreel et al. 2003; Johnson and Hill 1998; Kotwal et al. 1990) (Figure 1). The HSV membrane glycoprotein gC binds the complement factor C3 and protects cellfree virus from complement-mediated neutralization and inhibits the lysis of HSV-infected cells by antibody and complement (Lubinski et al. 1999). The poxviruses variola virus, vaccinia virus (VACV), and cowpox virus (CPXV) encode a secreted protein, known as viral complement control protein (VCP), that blocks the classical and alternative pathways of complement activation (Kotwal et al. 1990; Rosengard et al. 2002). Inactivation of the *VCP* gene in VACV causes virus attenuation in animal models, demonstrating an important role of this protein in preventing host defense mechanisms and a role for complement in antiviral immunity (Isaacs et al. 1992). Interestingly, inactivation of the CPXV VCP, known as inflammation modulatory protein (IMP), caused a substantial increase in the inflammatory response in infected mice compared to wild type CPXV infections (Miller et al. 1997). This illustrated that inhibition of the inflammatory response by viral proteins may reduce tissue damage and reduce the pathology associated with viral infection.

The complement system has the potential to cause extensive damage in the host cells and is therefore strictly controlled by both soluble and membrane proteins that block its activity. A strategy used by HIV is to recruit the soluble factor H that inhibits complement activation by interacting with the gp120–gp41 complex (Stoiber et al. 1996). Herpesvirus saimiri (HVS), a virus that infects monkeys, encodes a homologue of the inhibitor of the membrane attack complex CD59 that protects the infected cells from complement-mediated lysis (Rother et al. 1994). An alternative strategy is adopted by human retroviruses, VACV and human cytomegalovirus (HCMV). Instead of encoding homologues of host proteins, these viruses incorporate into the virion envelope host complement regulatory proteins, such as CD56 and CD59, that confer complement resistance to the virus particle (Saifuddin et al. 1995; Spear et al. 1995; Vanderplasschen et al. 1998).

EFFECTS ON SOLUBLE MEDIATORS OF THE IMMUNE SYSTEM

Modulation of IFN functions

IFNs were discovered because of their ability to protect cells from viral infection. IFNs can be classified as type I

(α and β) and type II (γ), and represent one of the first antiviral defense mechanisms to be activated after infection. The finding in recent years of anti-IFN strategies encoded by most viruses highlights the key role of IFNs against viral infection (Figure 2). IFNs are produced and secreted in response to viral infection and bind specific receptors which trigger intracellular pathways that activate antiviral mechanisms (Goodbourn et al. 2000; Katze et al. 2002). Two major pathways that induce an antiviral state in cells are up-regulated by IFN: the double-stranded RNA (dsRNA)-dependent protein kinase (PKR) and the 2′-5′ oligoadenylate system (2′-5′ OAS) that activates RNase L. In addition, IFNs have immunomodulatory activity that can influence the type of immune response mounted in response to infection.

Viruses block the activity of IFN at three different levels: (i) blockade of IFN binding to specific receptors; (ii) inhibition of signal transduction pathways induced by IFN; and (iii) inhibition of antiviral effector functions induced by IFN (Figure 2).

SECRETED VIRAL IFN RECEPTORS (IFNRS) AND IFN BINDING PROTEINS (IFNBPS)

Poxviruses encode proteins that are secreted from infected cells and bind with high affinity type I or type II IFN and prevent their interaction with IFNRs (Alcami 2003; McFadden and Murphy 2000) (Figure 2). This mechanism inhibits the initiation of IFN-mediated biological effects that lead to the establishment of an antiviral state in the cell or the activation of immune functions. Soluble receptors or binding proteins for other cytokines have been identified, mainly in the poxvirus family. Of particular relevance for IFN activity is the poxvirus IL-18 binding protein (vIL-18BP) which blocks the activity

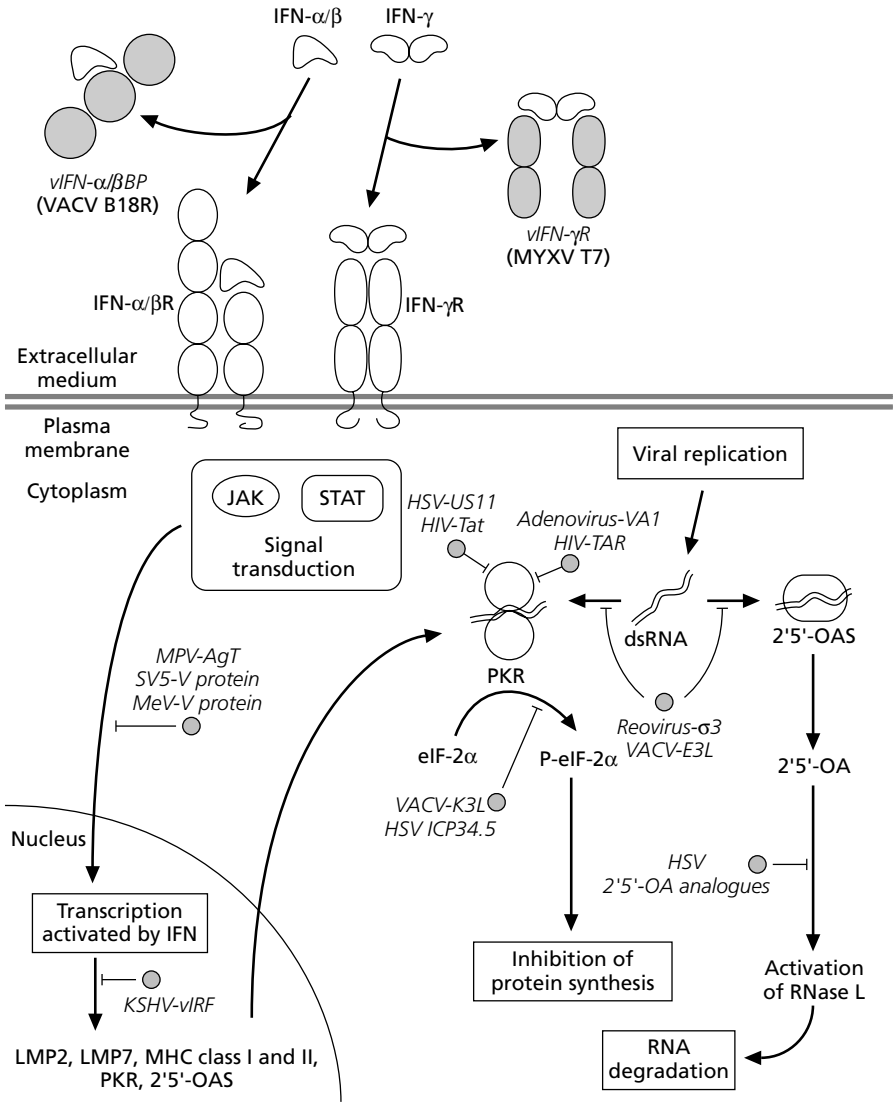

Figure 2 *Viral mechanisms to evade IFN activity*

of IL-18, a cytokine required together with IL-12 for the induction of IFN-γ (see below).

The viral IFN-γR (vIFN-γR) was first identified in myxoma virus (MYXV) and later in other members of the poxvirus family including VACV and CPXV (Alcami and Smith 1995; Mossman et al. 1995; Upton et al. 1992). The vIFN-γR has sequence similarity to the IFN binding domain of the cellular IFN-γR. The role of vIFN-γR during viral infection has been demonstrated by the attenuated phenotype a MYXV mutant lacking this IFN inhibitor (Mossman et al. 1996). A recent report describes a secreted IFN-γBP encoded by fowlpox virus that has no sequence similarity to known cellular IFN-γRs (Puehler et al. 2003). Because the IFN-γR of birds has not yet been characterized at the molecular level, this interesting finding raises the possibility that this virus may have hijacked an avian IFN-γR of different structure to the mammalian counterparts.

VACV and various poxviruses encode a secreted IFN-α/β receptor or binding protein (vIFN-α/βBP) that has very limited sequence similarity to the cellular counterparts (Colamonici et al. 1995; Symons et al. 1995). The vIFN-α/βBP has the unique property of binding to the cell surface after secretion (Alcami et al. 2000). The expression of viral decoy IFN-α/βRs at the cell surface of infected tissues will prevent the activation of IFN-mediated pathways more efficiently. A VACV mutant lacking the *vIFN-α/βBP* gene is attenuated in mice and its ability to grow in tissues and spread to other organs is impaired (Symons et al. 1995).

INTERFERENCE WITH SIGNAL TRANSDUCTION INDUCED BY IFNS

The interaction of IFNs with specific receptors at the cell surface triggers a complex cascade of intracellular pathways through janus kinase (JAK) and signal transducers and activators of transcription (STAT) pathways (Goodbourn et al. 2000; Katze et al. 2002) (Figure 2). These signaling events result in the up-regulation of cellular proteins that limit viral replication in several ways. Some of the genes upregulated by IFN are the low-molecular-weight protein (LMP) 2 and LMP7 subunits of the proteasome, involved in the generation of viral peptides for MHC class I molecules, the molecules that present viral peptides to T cells. Other genes up-regulated by IFNs are protein kinase dsRNA (PKR) and 2′5′-OAS which confer an antiviral state in cells.

Some viral proteins interfere with the IFN signaling cascade (Goodbourn et al. 2000; Katze et al. 2002). For example, the T antigen of murine polyomavirus (MPV) binds to and inactivates JAK1 (Weihua et al. 1998), whereas the protein V from simian virus 5 (SV-5) interacts with STAT1 and induces its degradation by the proteasome (Didcock et al. 1999). Other paramyxovirus V proteins target different components of the IFN signaling pathway. Type II human parainfluenza virus V protein targets STAT2, mumps virus V protein targets both STAT1 and STAT3, and measles virus (MeV) V protein causes a defect in STAT nuclear accumulation and STAT-inducible transcription (Nishio et al. 2002; Palosaari et al. 2003; Parisien et al. 2001; Ulane et al. 2003). Kaposi's sarcoma-associated herpesvirus (KSHV) uses a different mechanism by encoding a homologue of the IFN regulatory factor (IRF) that represses the IFN-mediated transcriptional activation of host genes (Zimring et al. 1998).

VIRAL MODULATION OF IFN EFFECTOR FUNCTIONS

One of the best-characterized antiviral effects of IFN is the induction of the PKR and 2′5′-OAS pathways that lead to the blockade of viral gene expression in the cell (Gale and Katze 1998; Goodbourn et al. 2000; Katze et al. 2002) (Figure 2). The replication and transcription of viral genomes leads to the formation of dsRNA that activates PKR, which phosphorylates the translation initiation factor 2α (eIF-2α) causing its inactivation and the subsequent arrest of protein synthesis in infected cells. Viral mechanisms that prevent the activation of PKR include: (i) proteins encoded by reovirus (σ3) and VACV (E3L) that bind dsRNA; (ii) RNAs encoded by adenovirus (VAI) and HIV (TAR) that bind PKR but do not activate the enzyme; and (iii) proteins encoded by HSV (US11) and HIV (Tat) that bind directly to PKR and inactivate the enzyme. An alternative strategy to block the PKR pathway is to prevent the phosphorylation of eIF-2α. VACV and other poxviruses encode an eIF-2α homologue, the K3L protein in VACV, that acts as a substrate of PKR and prevents phosphorylation of eIF-2α. An alternative strategy is illustrated by the HSV IC34.5 protein which activates protein phosphatase 1α that removes the phosphate groups from eIF-2α.

The formation of dsRNA during viral replication also activates the enzyme 2′5′-OAS, producing 2′5′-OA which in turn activates RNase L and the degradation of RNA within the infected cell, causing the blockade of viral replication. HSV produces analogues of 2′5′-OA which bind RNaseL and inhibit this pathway (Goodbourn et al. 2000). The proteins σ3 from reovirus and E3L from VACV bind dsRNA and thus inhibit the activation of 2′5′-OAS as well as PKR (see above).

Modulation of cytokine networks

Cytokines are a family of molecules that initiate and orchestrate the immune response, and include growth factors, IFNs, tumor necrosis factor (TNF), ILs, and chemokines. Cytokines are normally secreted from cells, although some are expressed at the cell surface, and activate specific responses in cells expressing the appropriate receptors. Immune cells use this complex network of ligands and receptors to orchestrate the immune response. In this way, the production of a particular cytokine after viral infection will determine the type of

immune and inflammatory response that takes place. In addition, some cytokines such as IFN and TNF may act directly on infected cells and restrict virus replication.

The importance of cytokines in antiviral defense is highlighted by the number of mechanisms that viruses encode to block their activity (Alcami and Koszinowski 2000; Tortorella et al. 2000). The purpose of many of the viral anticytokine strategies is to down-regulate the immune responses to infection. However, it is important to consider that some viruses replicate in immune cells and these may be taking advantage of the effects that cytokines have on cell physiology to enhance the ability of cells to support viral replication, thus promoting viral replication rather than evading the immune system. Viruses may block the synthesis and maturation of cytokines or may modulate cytokine signaling in the target cells. Large DNA viruses such as poxviruses and herpesviruses have captured in their genomes genes encoding host cytokines and cytokine receptors (Alcami 2003; McFadden and Murphy 2000; Seet et al. 2003) (Figures 3 and 4).

VIRAL MODULATION OF CYTOKINE EXPRESSION AND ACTIVATION

Mechanisms that modulate the synthesis of cytokines have been described (Figure 3). African swine fever virus (ASFV) replicates in macrophages, one of the major cytokine producers in the immune system, and offers a good example to illustrate the control of cytokine production by viruses. ASFV encodes an IκB homologue that interacts with the transcription factors nuclear factor κB (NF-κB) and nuclear factor activated T cell (NFAT) and prevents the transcription of cytokine genes (Miskin et al. 1998). During virus entry into cells, the interaction of MeV with its cellular receptor CD46, a complement regulatory protein that protects cells from lysis by complement, blocks the production of IL-12, a potent inducer of IFN-γ and cellular responses. The CPXV protein cytokine response modifier A (CrmA) was found to inhibit the IL-1β converting enzyme (ICE) or caspase 1, which proteolytically cleaves the precursor form of proinflammatory cytokine IL-1β (pro-IL-1β) to generate mature, active IL-1β (Ray et al. 1992). CPXV CrmA may also prevent the maturation of IL-18, which is also proteolytically cleaved by ICE, and is an inhibitor of apoptosis (see below).

VIRAL MODULATION OF CYTOKINE SIGNAL TRANSDUCTION

There are several examples of viruses that inhibit cytokine-induced intracellular pathways, such as some of the anti-IFN mechanisms discussed above. The interaction of TNF and Fas ligand (FasL) with their receptors induce signaling that lead to an apoptotic response that some viruses are able to block (see below). Adenoviruses interfere with signaling induced by TNF at different levels (Mahr and Gooding 1999). The poxvirus VACV encodes two intracellular proteins (A52R and A46R) that block signaling mediated by Toll-like and IL-1 receptors by mimicking intracellular regulatory domains of these receptors (Bowie et al. 2000; Harte et al. 2003). The Toll-like receptor pathway is important in NF-κB activation and amplification of inflammatory signals.

Lastly, some viruses may subvert cytokine-mediated signaling for their own benefit. The latent membrane

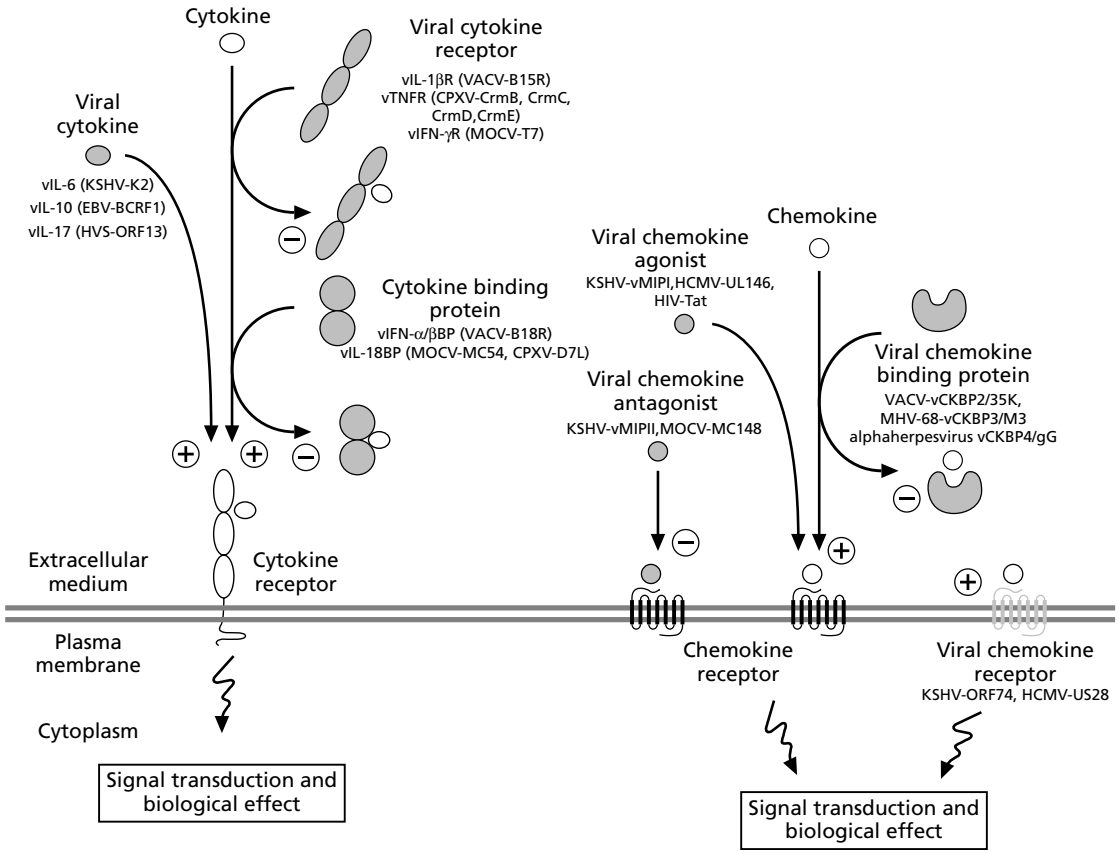

Figure 4 *Cytokines and cytokine receptors encoded by viruses*

protein 1 (LMP1) of Epstein–Barr virus (EBV), a virus that establishes latency in B cells, best illustrates this (Figure 3). LMP1 is a membrane protein that lacks sequence similarity to members of the TNF receptor (TNFR) superfamily but has a short cytoplasmic sequence that binds TNFR activating factors (TRAF), components of the TNFR and CD40 transduction machinery. During the immune response, binding of trimeric TNF to its receptor induces receptors multimerization and recruitment of TRAFs followed by the initiation of a signaling cascade leading to either B cell proliferation or the induction of apoptosis. In EBV-infected cells, the recruitment of TRAFs by LMP1 induces biological responses such as cell proliferation that may enhance virus replication (Farrell 1998). In this way, EBV takes advantage of a B-cell activation pathway to ensure survival of the infected cell that carries the latent viral genome.

Molecular mimicry: viral cytokines and cytokine receptors

The sequence of the genome of large DNA viruses (poxviruses and herpesviruses) showed that some viral proteins have sequence similarity to ligands and receptors of the cytokine family (Alcami 2003; McFadden and Murphy 2000; Seet et al. 2003) (Figure 4). The sequence similarity suggests that, during evolution, viruses may have 'stolen' host genes that play critical roles in the immune system and incorporated them into their genomes. Viruses may have later modified the function of these host proteins for their own benefit since very often the biological properties of the viral proteins differ from their cellular counterparts.

VIRAL CYTOKINES

Viral cytokines act normally as agonists, driving the immune response in a direction that will be more beneficial for the virus (Figure 4). The VACV epidermal growth factor homologue (VGF) was the first viral cytokine identified. VGF activates cell growth and promotes viral replication, but an immune-related function has not been ascribed to it (McFadden et al. 1994). The EBV-encoded IL-10 homologue (vIL-10) was the first viral cytokine identified with immunomodulatory activity (Hsu et al. 1990). Genes encoding related vIL-10s have also been identified in other viruses. It has been shown that the EBV vIL-10 suppresses cellular immunity by inhibiting the production of IFN-γ, but has lost the immunostimulatory properties of the host counterpart. Other viral cytokines are the IL-6 homologue (vIL-6) encoded by KSHV (Moore et al. 1996) and the IL-17

homologue (vIL-17) encoded by HVS (Yao et al. 1995). In addition to their immunomodulatory activity, vIL-6 and vIL-17 may also promote the proliferation of B and T cells, respectively. These are the major host cell types for these viruses and their increased presence in infected tissues may favor viral replication.

The identification of semaphorin homologues (vSEMAs) in poxvirus and herpesvirus genomes was somehow surprising because semaphorins were described as chemoattractants and chemorepellents involved in axonal guidance during nervous system development, and only CD100 had been identified as a semaphorin involved in the immune system (Spriggs 1999). Investigations on the vSEMA encoded by VACV and ectromelia virus (ECTV) led to the identification of a specific receptor in macrophages that triggers expression of cytokines. The pro-inflammatory activity of vSEMA has been observed in mice infected with a VACV expressing an active protein (Gardner et al. 2001). However, the precise role of vSEMA in immune modulation during viral infection remains to be determined.

SECRETED VIRAL CYTOKINE RECEPTORS

Viral genes encoding soluble cytokine receptors have been identified mainly in the poxvirus family and a few examples have been recently described in the herpesvirus family (Figure 4). Viral cytokine receptors lack the transmembrane and cytoplasmic domains of the host counterparts, are secreted in large quantities from infected cells and have the ability to bind with high affinity the cognate cytokine and to block its activity. The poxvirus soluble cytokine receptors were initially identified because of their sequence similarity to the extracellular binding domain of their host counterparts. A second class of cytokine receptors, known as binding proteins, have very limited sequence similarity to the host cytokine receptors and were identified in cytokine binding or activity assays.

The soluble TNFR (vTNFR) M-T2 encoded by MYXV was the first viral cytokine receptor identified (Smith et al. 1991). Four different genes encoding vTNFRs were subsequently identified in other poxviruses such as CPXV, VACV, and ECTV, and were designated CrmB, CrmC, CrmD, and CrmE (Hu et al. 1994; Loparev et al. 1998; Saraiva and Alcami 2001; Smith et al. 1996). These vTNFRs have different molecular size, are produced at different times of infection, and in some cases show distinct binding properties. The reasons for the existence in poxvirus genomes of such a variety of vTNFRs apparently targeting the same ligand are unknown. Further complexity has been added by the recent description of a secreted protein encoded by Tanapox virus that binds TNF but has no sequence similarity to TNFRs (Brunetti et al. 2003). It appears that different poxviruses encode related, but distinct, proteins to block TNF activity extracellularly. Clinical isolates of HCMV, but not laboratory strains, encode a membrane TNFR homologue (UL144) related to herpesvirus entry mediator (HVEM) that is retained intracellularly (Benedict et al. 1999). No ligand has been identified for this protein and its function remains to be determined. Maybe this membrane TNFR subverts TNF-mediated pathways in the infected cell.

Another member of the TNFR superfamily has been recently identified in CPXV and ECTV: a secreted and shorter version of CD30 (vCD30) (Panus et al. 2002; Saraiva et al. 2002). Viral cytokine receptors function as decoy receptors and, accordingly, vCD30 blocks the interaction of CD30 to CD30 ligand (CD30L). However, in this case, the ligand is only expressed at the cell surface and vCD30 induces reverse signaling in CD30L-expressing cells. The function of vCD30 in the context of infection has not been elucidated, but vCD30 has been shown to down-regulate type 1 cytokine-mediated inflammatory responses in mice, a property that may help the virus to evade an efficient antiviral response (Saraiva et al. 2002).

The viral IL-1β receptor (vIL-1βR) is related to the human type II IL-1R and acts as a decoy receptor (Alcami and Smith 1992; Spriggs et al. 1992). In contrast to the membrane IL-1Rs encoded by the host, the vIL-1βR binds exclusively IL-1β and not IL-1α or IL-1 receptor antagonist. Deletion of this gene in VACV causes attenuation when the virus is administered intracranially (Spriggs et al. 1992) but leads to enhanced virulence associated with fever and accelerated death in mice infected through the respiratory route, a natural route of poxvirus transmission (Alcami and Smith 1992; Alcami and Smith 1996). The enhanced virulence observed after deletion of the vIL-1βR from VACV illustrates that the role of some viral immunomodulatory proteins may be to reduce pathology induced by excess production of cytokines, in this case IL-1β, during infection rather than to cause immunosuppression.

VIRAL CYTOKINE-BINDING PROTEINS

IL-18 is a pro-inflammatory cytokine that is required, together with IL-12, for induction of IFN-γ and the generation of an efficient cellular response against viral infection. The viral IL-18 binding protein (vIL-18BP) encoded by several poxviruses is homologue of the human IL-18BP but has no sequence similarity to membrane IL-18 receptors (Figure 4). The vIL-18BP is an effective scavenger of IL-18 and down-regulates IFN-γ production and NK responses in ECTV-infected mice (Born et al. 2000; Smith et al. 2000). Interestingly, the vIL-18BP is also expressed by molluscum contagiosum virus (MOCV), a poxvirus that causes benign skin tumors and persists in the skin for months without inducing an inflammatory response (Smith et al. 2000; Xiang and Moss 1999). The vIL-18BP is the only

cytokine receptor encoded by MOCV and may be responsible in part for the lack of inflammation in MOCV lesions.

The EBV-encoded colony stimulating factor 1 binding protein (vCSF-1BP) has limited sequence similarity to the cellular counterpart and is the only secreted cytokine binding protein identified in herpesvirus (Strockbine et al. 1998). It has been proposed that vCSF-1BP may modulate the response of macrophages during EBV infection. An interesting example of a viral secreted cytokine binding protein that binds ligands that interact with different host receptors is the orf virus-encoded protein that binds granulocyte–macrophage colony stimulating factor (GM-CSF) and IL-2. The role of this protein during infection of Orf virus, which causes skin lesions in sheep, goat, and man, has not been defined (Deane et al. 2000).

Modulation of chemokine networks

Chemokines are a family of small molecular size cytokines that induce cell migration and other biological effects, such as cell differentiation and angiogenesis, and control the trafficking of cells of the immune system throughout the body (Baggiolini 1998). There are more than 40 chemokines identified that can be structurally classified as CC, CXC, C or CX3C, according to the number of amino acids found between the first cysteine residues. Chemokines mediate their biological effects by binding and signaling through G-protein coupled receptors, proteins that have seven transmembrane domains. More than 20 chemokine receptors have been identified. Chemokines also interact with glycosaminoglycans (GAG) to enable their presentation at the surface of the endothelium and the establishment of chemokine gradients in tissues. There is recent evidence that chemokine–GAG interactions are required for the activity of chemokines in vivo (Proudfoot et al. 2003). The immune system makes the decision of which type of immune cell will migrate in response to infection or inflammation depending on the chemokine that is produced and the cell type that expresses the appropriate receptor. Thus the chemokine system plays a critical role in determining the type of immune response initiated after infection.

Viruses, mainly herpesviruses and poxviruses, utilize three mechanisms to modulate chemokine activity: expression of chemokine homologues, of chemokine receptor homologues, and of secreted chemokine binding proteins (Alcami 2003; Lalani et al. 2000; McFadden and Murphy 2000; Murphy 2001) (Figure 4). The function of these viral proteins during the infectious cycle is diverse and is discussed below (Figure 4).

VIRAL CHEMOKINE HOMOLOGUES

Some viruses encode chemokine homologues that are secreted from infected cells and function as agonists or antagonists (Figure 4). The chemokine homologues vMIP-II from KSHV and MC148 from MOCV bind to chemokine receptors but do not transduce signals (Boshoff et al. 1997; Damon et al. 1998; Kledal et al. 1997; Krathwohl et al. 1997). These antagonists block the binding of endogenous chemokines to their specific receptor and inhibit the migration of immune cells into infected tissues. By contrast, some viral chemokines have agonistic activity and induce cell migration into areas of infection, and thus their function may be unrelated to immune evasion. Viruses encoding chemokine agonists take advantage of the chemokine system to recruit to areas of infection immune cells that represent good targets for viral replication in order to enhance viral dissemination. HCMV UL146, known as vCXC-1, induces neutrophil chemotaxis by binding to CXCR2 and may account for the association of neutrophils with HCMV infections (Penfold et al. 1999). Human herpesvirus 6 (HHV-6) U83 induces monocyte migration that may favor the establishment of viral latency and persistence in the infected host (Zou et al. 1999). Another example of chemokine mimetics is the protein Tat from HIV that shows limited sequence similarity to chemokines. HIV Tat is a chemoattractant for monocytes and may enhance replication and spread of HIV in infected individuals (Albini et al. 1998). Direct evidence for a role of viral chemokine agonists in vivo comes from studies with murine cytomegalovirus (MCMV) mutants lacking the chemokine genes M131/129. The MCMV chemokine is encoded by the m131 orf and is expressed as a protein fused to the m129 orf. The isolated synthetic m131 product attracts activated macrophages by engaging a receptor related to human CCR3 (Saederup et al. 1999). A mutant MCMV lacking the function shows reduced spread to salivary glands, indicating that monocyte attraction serves for virus trafficking.

The role of the viral chemokines encoded by KSHV in viral dissemination has not been fully defined but they may play a role in pathogenesis due to their angiogenic properties that may cause the enhanced vascularization observed in Kaposi's sarcoma lesions (Boshoff et al. 1997). In addition, the KSHV chemokines are chemoattractants for Th2 polarized T cells and may influence the type of immune response initiated after viral infection (Dairaghi et al. 1999; Endres et al. 1999; Sozzani et al. 1998; Stine et al. 2000).

An interesting addition to chemokine mimicry by viruses is the glycoprotein G (gG) of respiratory syncytial virus which has partial sequence similarity to fractalkine and chemokine-like activity (Tripp et al. 2001). This property of gG may be used to facilitate virus entry into cells and to modulate the host immune response.

VIRAL CHEMOKINE RECEPTOR HOMOLOGUES

There are many examples of chemokine receptor homologues in members of the herpesvirus family and some

in the poxvirus family (Figure 4). These proteins are expressed at the surface of infected cells and their ability to neutralize large amounts of chemokine may be limited. Some viral chemokine receptors have been found to bind chemokines and to transduce signals, and they may function to modulate the physiological state of the cell by activating chemokine-mediated signaling pathways. The ORF74 protein from KSHV is constitutively active and binding of chemokines can modulate the activation status of the receptor (Arvanitakis et al. 1997; Rosenkilde et al. 1999). Expression of this receptor in cell culture induces cell proliferation and may favor the persistence of KSHV. Transgenic mice expressing ORF74 develop Kaposi's sarcoma-like lesions (Arvanitakis et al. 1997; Yang et al. 2000). The possibility that expression of KSHV ORF74 may contribute to neoplasia through a paracrine effect has been proposed but may be difficult to demonstrate in KSHV-infected individuals. ORF74 is one of the best examples to illustrate the direct effect that viral immunomodulatory proteins may have on the pathology caused by viral infection. Four chemokine receptor homologues are encoded by HCMV: UL78, UL33, US27 and US28. MCMV encodes the viral chemokine receptors M33 and M78, which are homologous to their counterparts in HCMV. HCMV US28 can modify the chemokine environment of infected cells by sequestering and internalizing chemokines and depleting them from the medium (Bodaghi et al. 1998). Similarly, HHV-6 UL51 reduces extracellular accumulation of chemokines by sequestration, but also by a novel mechanism of down-regulation of CCL5 (RANTES) transcription (Milne et al. 2000). The potential contribution of viral chemokine receptors to pathology is also illustrated by the fact that HCMV US28 expression on the cell surface mediates cell adhesion, vascular smooth muscle cell migration, and it is thought to be related to vascular disease (Streblow et al. 1999). Evidence for a role for viral chemokine receptors in virus replication in vivo was demonstrated first for MCMV M33 (Davis-Poynter et al. 1997).

VIRAL CHEMOKINE BINDING PROTEINS (VCKBP)

The third class of viral chemokine inhibitors are the vCKBPs from poxviruses and herpesviruses that sequester chemokines in solution without apparent sequence similarity to host chemokine receptors (Seet and McFadden 2002; Smith et al. 2003) (Figure 4).

The MYXV M-T7 protein (vCKBP-1) is a soluble vIFN-γR with sequence similarity to human IFN receptors that was later found to interact also with chemokines. MYXV M-T7 binds a broad spectrum of chemokines and it has been proposed that it prevents the interaction of chemokines with GAGs and their correct presentation to leukocytes (Lalani et al. 1997). vCKBP-2 was identified in the medium from cultures infected with MYXV, VACV, or CPXV (Alcami et al. 1998; Graham et al. 1997; Smith et al. 1997). In this case, the protein binds CC chemokines with high affinity and neutralizes their effect by preventing the binding of chemokines to specific receptors in leukocytes. The protein M3 (vCKBP-3) encoded by murine gammaherpesvirus 68 (MHV-68) was found to bind a broad range of chemokines, including C, CC, CXC, and CX3C chemokines, and to block their interaction with cellular receptors (Parry et al. 2000; van Berkel et al. 2000). More recently, another family of vCKBPs has been identified in alphaherpesviruses (Bryant et al. 2003). gG is a membrane protein, present in the virions of some alphaherpesviruses, that is proteolytically cleaved and released to the extracellular space. Broad spectrum chemokine binding activity has been found in gG encoded by some alphaherpesviruses. This vCKBP blocks the interaction of chemokines to both specific chemokine receptors and GAGs.

The vCKBPs have amino acid sequences unrelated to chemokine receptors or other vCKBPs. Interestingly, the existing experimental data indicates that vCKBPs mimic the interaction of chemokines to their membrane receptors, in spite of the lack of amino acid sequence similarity (Alexander et al. 2002; Beck et al. 2001; Seet et al. 2001; Webb et al. 2003). The crystal structure of the poxvirus 35 kDa and MHV-68 M3 vCKBPs have been reported (Alexander et al. 2002; Carfi et al. 1999).

The generation of relevant virus mutants lacking specific vCKBPs and the infection of rabbits or mice suggest that these proteins may block chemokine-mediated leukocyte infiltration into infected areas in vivo (Graham et al. 1997; Lalani et al. 1999; Mossman et al. 1996; Reading et al. 2003; van Berkel et al. 2002). Interestingly, expression of the vCKBP-2 from VACV attenuates the virus in a murine intranasal model, probably due to a reduced inflammatory reaction to infection (Reading et al. 2003). In addition, MHV-68 M3 has been proposed to be required by the virus to establish virus latency and to enable persistence of the virus in the host (Bridgeman et al. 2001).

EVASION OF ANTIGEN PRESENTATION AND THE CELLULAR RESPONSE

The variability of viral antigens, discussed above in the context of the humoral response, is also relevant in the evasion of CTL recognition. Peptides derived from mutated viral proteins may lose their ability to bind to MHC molecules and be presented to the immune system. However, those viruses such as herpesviruses that establish infections for the life of the host but have a very low mutation rate must identify alternative mechanisms to persist in the presence of a vigorous immune response (Figure 5).

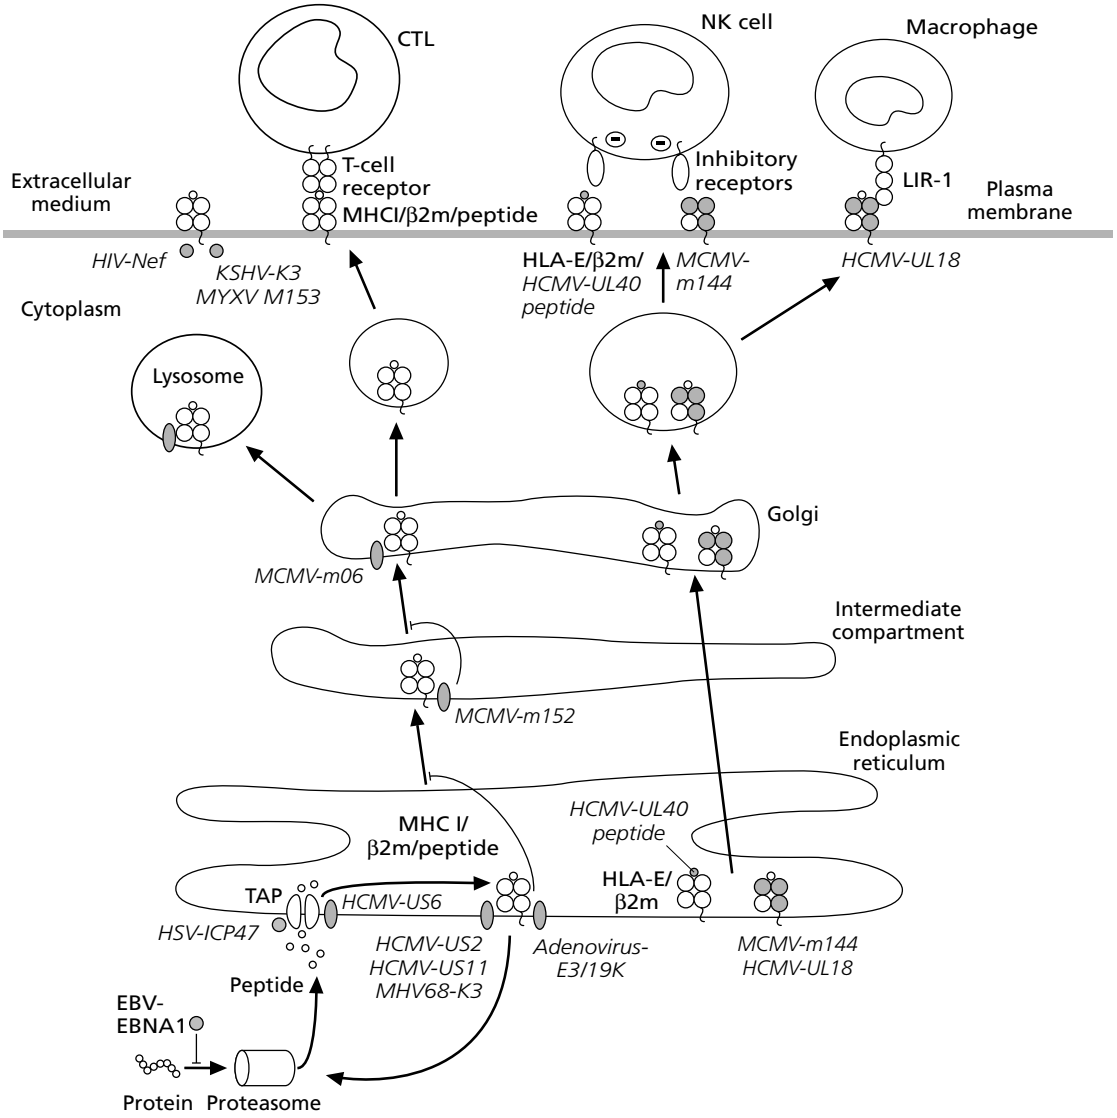

Figure 5 *Viral inhibition of antigen presentation and NK cell response*

Blockade of antigen presentation mediated by MHC class I molecules

MHC class I molecules display peptides at the cell surface derived from proteins expressed in the cell for recognition by the immune system (Figure 5). Viral proteins synthesized in the infected cell are degraded in the cytosol mostly by the proteasome, the major intracellular proteolytic complex, and the peptides generated are translocated to the lumen of the endoplasmic reticulum (ER) by transporters associated with antigen processing (TAP). The peptides associate with MHC class I molecules and β2-microglobulin to form a complex that is transported to the cell surface through the Golgi apparatus. The presentation of peptides derived from viral proteins activate specific CTLs that may destroy the infected cell. Herpesviruses are particularly well prepared with mechanisms that inhibit almost every step of the antigen presentation pathway (Figure 5) (Fruh et al. 1999; Johnson and Hill 1998; Yewdell and Hill 2002).

The nuclear antigen EBNA1 encoded by EBV has a long segment of repeated glycine and alanine residues that prevents protein degradation by the proteasome (Levitskaya et al. 1995). The HSV protein ICP47 and the HCMV US6 bind to TAP and inhibit peptide translocation from the cytosol to the ER lumen (Ahn et al. 1997; Hengel et al. 1997; Lehner et al. 1997; York et al. 1994). While ICP47 is a cytosolic protein, US6 is a transmembrane glycoprotein that binds TAP on the lumenal side of the ER. In the ER, MHC class I molecules associate with TAP as part of a peptide loading complex that includes tapasin. The adenovirus E3/19K protein binds TAP and interferes with the ability of tapasin to bring class I molecules and TAP together (Bennett et al. 1999).

The degradation of newly synthesized MHC class I molecules is an alternative mechanism. The HCMV US2 and US11 proteins are membrane glycoproteins that interact with lumenal domain of MHC class I molecules and cause them to be transported back to the cytosol, where MHC class I molecules are ubiquitinylated and destroyed by the proteasome (Wiertz et al. 1996a; Wiertz et al. 1996b). The molecular mechanism behind this immune evasion strategy has attracted much interest because it sheds light on an important transport system from the ER to the cytosol. The K3 protein of MHV-68 is a ubiquitin ligase that ubiquitylates the cytoplasmic tail of ER-resident class I molecules and targets them for destruction in the cytosol (Boname and Stevenson 2001). The related K3 and K5 proteins encoded by KSHV also targets class I, but in this case the viral proteins target cell surface class I molecules for degradation (see below).

Several viruses block trafficking of class I molecules to the cell surface. The adenovirus E3/19K protein and the m152 protein from MCMV block the transport of peptides complexed to MHC class I molecules and β2-microglobulin (β2m) at different levels (Jefferies and Burgert 1990; Ziegler et al. 1997). The m06 protein from MCMV binds MHC class I molecules and directs them to the lysosome for degradation, due to the presence of a di-leucine motif in its cytoplasmic tail (Reusch et al. 1999). HIV Nef removes MHC class I molecules from the cell surface and directs them to the trans-Golgi network, due to the interaction of Nef with the PACS-1 protein which sorts molecules to the trans-Golgi network (Piguet et al. 2000). The KSHV K3 and K5 proteins ubiquitylate MHC class I and this signals class I internalization from the plasma membrane for endosomal degradation (Hewitt et al. 2002). A related protein encoded by MYXV, named M153, has been shown to target class I molecules both at the cell surface and in the post-Golgi compartment for retention and degradation in the lysosome. MYXV M153 has also been implicated in the depletion from the cell surface of CD4, the coreceptor in MHC class II-restricted antigen-induced T-cell activation, and Fas, which triggers apoptosis after interaction with FasL (Guerin et al. 2002; Mansouri et al. 2003).

The significance of the viral interference with CTL function is not clear in the context of the infected host since most of these mechanisms have been identified in cell cultures in vitro. A modest role for MCMV m152 in CTL escape in vivo has been reported, but no major effect on the virus replication was observed (Krmpotic et al. 2002). In the case of MHV-68, a mutant virus lacking K3 grows normally in the initial lung infection but does not establish latency in the spleen, which is controlled by CTLs (Stevenson et al. 2002). The in vivo advantage of CTL escape mutants in simian immunodeficiency virus (SIV) and HIV expressing mutant CTL epitopes has been established (Allen et al. 2000; Goulder et al. 2001). Also, there is evidence that the ability of SIV Nef to down-regulate class I molecules is important in vivo (Munch et al. 2001).

Blockade of antigen presentation by class II MHC molecules

In contrast to MHC class I molecules, which present peptides derived from newly synthesized proteins, MHC class II molecules present peptides derived from exogenous antigens that are internalized and degraded in the lysosome. Only a few viral proteins have been found to block this pathway of antigen presentation. The US2 protein from HCMV induces the degradation of MHC class II molecules in the proteasome and HIV Nef interferes with the transport of MHC class II molecules to compartments where they associate with peptides before they reach the cell surface (Tomazin et al. 1999). HCMV US3 has also been shown to cause intracellular MHC class I retention (Hegde et al. 2002).

Evasion of the lysis of virus-infected cells by NK cells

NK cells constitute one of the first lines of defense against viruses. These cells posses specific activating receptors that recognize carbohydrate at the cell surface and induce their cytolytic activity. The NK cells also express other receptors, known as inhibitory receptors, that recognize MHC class I molecules and transduce a signal that blocks their cytotoxic machinery. In this way, NK cells recognize healthy cells expressing normal levels of MHC class I molecules and destroy cells that do not express class I molecules. The down-regulation of MHC class I molecules by some viruses prevents the specific recognition of the infected cell by CTLs, but may have dramatic consequences by increasing the susceptibility of virus-infected cells to NK cell lysis (Orange et al. 2002).

To solve this problem, some viruses encode homologues of MHC class I molecules (Figure 5). The MCMV protein m144 forms a complex with β2-microglobulin and is expressed at the cell surface where it interacts with NK cells and induces inhibitory signals that prevent the lysis of the infected cell (Farrell et al. 1997). A virus lacking m144 is attenuated in mice but is similar to wild-type virus in mice depleted of NK cells, suggesting that m144 controls NK activity in vivo. The role of the HCMV protein UL18, a class I homologue, in evasion of NK cell lysis is controversial (Reyburn et al. 1997). The demonstration that HCMV UL18 interacts with a receptor in macrophages suggested that these class I homologues may also modulate the activation of other immune cells that play a critical role against viral infections (Cosman et al. 1997). MOCV, unlike other poxviruses, establishes persistent infections in the skin

and encodes an MHC class I homologue of unknown function (Senkevich and Moss 1998).

HLA-E is an MHC class I molecule that presents peptides derived from signal sequences from other MHC class I molecules, interacts with an inhibitory receptor in NK cells, NKG2A, and prevents lysis mediated by NK cells (Figure 5). In this way, HLA-E 'informs' the NK cells on global levels of MHC class I expression in the cell. To compensate for the low levels of MHC class I molecules in the infected cell, HCMV encodes a signal peptide, present in the UL40 protein, that specifically binds HLA-E. In this way, normal levels of HLA-E-peptide complexes at the cell surface are present in the infected cell and protect it from NK cell attack (Tomasec et al. 2000).

The MCMV protein m152 interferes with class I antigen presentation (see above). In addition, it was found that m152 also reduces the cell surface levels of the class I-like molecules RAE and H60, which serve as ligands for the NK cell activating receptor NKG2D (Krmpotic et al. 2002). An MCMV mutant lacking m152 was more susceptible to NK cell lysis.

A soluble form of HCMV UL16 binds to a family of human glycosylphosphatidylinositol-linked receptors and MHC class I-related proteins know as UL16 binding proteins (ULBP). The NK cell activating receptor NKG2D binds ULBPs, and this interaction is blocked in the presence of soluble UL16 (Cosman et al. 2001). These data suggest a mechanism by which UL16 may inhibit NK cell function.

Viral inhibition of dendritic cell (DC) functions

Antigen presenting cells (APC), usually DCs, capture antigen at the site of infection and migrate to the lymph nodes where they interact and activate naïve T cells. The T cells acquire a mature phenotype and can migrate to infected tissues where they can activate effector functions with antiviral properties, such as cytolytic activity or the release of antiviral cytokines. The inhibition of DC function by viruses is predicted to have a major impact in antiviral immunity.

By infecting DCs viruses may interfere with class I MHC processing and presentation would inhibit the role of DCs in immunity. A number of reports have shown that some viruses interfere with the maturation of DCs, which is necessary for DCs to present antigens to T cells and to activate them. DCs infected by MeV inhibit rather than promote the proliferation of T cells and express the apoptosis inducing ligand TRAIL (Grosjean et al. 1997; Vidalain et al. 2000). The interference of MeV with DC function is thought to be largely responsible for the generalized immunosuppression associated with MeV infection. Inhibition of DC maturation has been reported for HSV, MCMV, and HCMV (Andrews et al. 2001; Moutaftsi et al. 2002; Salio et al. 1999).

APOPTOSIS

Apoptosis or programmed cell death can be activated in several ways, including by TNF superfamily members, irradiation, inhibitors of cell cycle or infectious agents such as viruses. The sequential activation of a family of proteases known as caspases plays a central role in the control of the apoptotic response (Figure 6). Apoptosis can be considered an innate mechanism of defense against viral infection that limits virus replication. In addition, CTLs and NK cells destroy virus-infected cells by inducing apoptosis as a result of the production of cytokines such as TNF, the activation of Fas at the cell surface by FasL or the secretion of perforin that enables other secreted proteins (granzymes) to enter the cell. Although the apoptotic response limits virus replication when activated at early times of infection, the induction of apoptosis may also favor the release of virus particles and viral dissemination within the host under some circumstances. Many cellular proteins involved in the control of apoptosis are targets of viral anti-apoptotic mechanisms (Figure 6) (Benedict et al. 2002; Everett and McFadden 1999).

Blockade of signaling through TNFR and Fas

The soluble vTNFRs encoded by poxviruses, discussed above, prevent the binding of TNF to its receptor and the induction of TNF-mediated apoptosis (Alcami 2003; McFadden and Murphy 2000; Seet et al. 2003) (Figure 6). The interaction of TNFRs and Fas with their respective ligands induces the binding of cytoplasmic factors that interact through death domains (DD) and death effector domains (DED) present in adaptor proteins, such as TRADD (TNF-receptor-activated death domain) and FADD (Fas-associated death domain), and in some caspases. These factors initiate a cascade of interactions that culminate with the activation of caspases and the induction of apoptosis. MOCV and KSHV encode vFLIPs (FLICE or caspase 8-inhibitory proteins) that have death domains and prevent signal transduction through receptors for TNF and FasL (Bertin et al. 1997; Thome and Tschopp 2001). The HCMV *UL36* gene product vICA associates with caspase 8 and blocks its activation, but its sequence is unrelated to FLIPs (Skaletskaya et al. 2001). Adenoviruses produce a number of proteins encoded by the E3 region that inhibit TNF- and Fas-mediated apoptosis (Wold et al. 1999). The adenovirus receptor internalization and degradation (RID) complex, formed by the E3/10.4K and E3/14.5K proteins, induces internalization and subsequence degradation in lysosomes of TNFR and Fas. As a result of this, the infected cell becomes resistant to TNFR- and Fas-mediated apoptosis (Burgert et al. 2002; McNees and Gooding 2002).

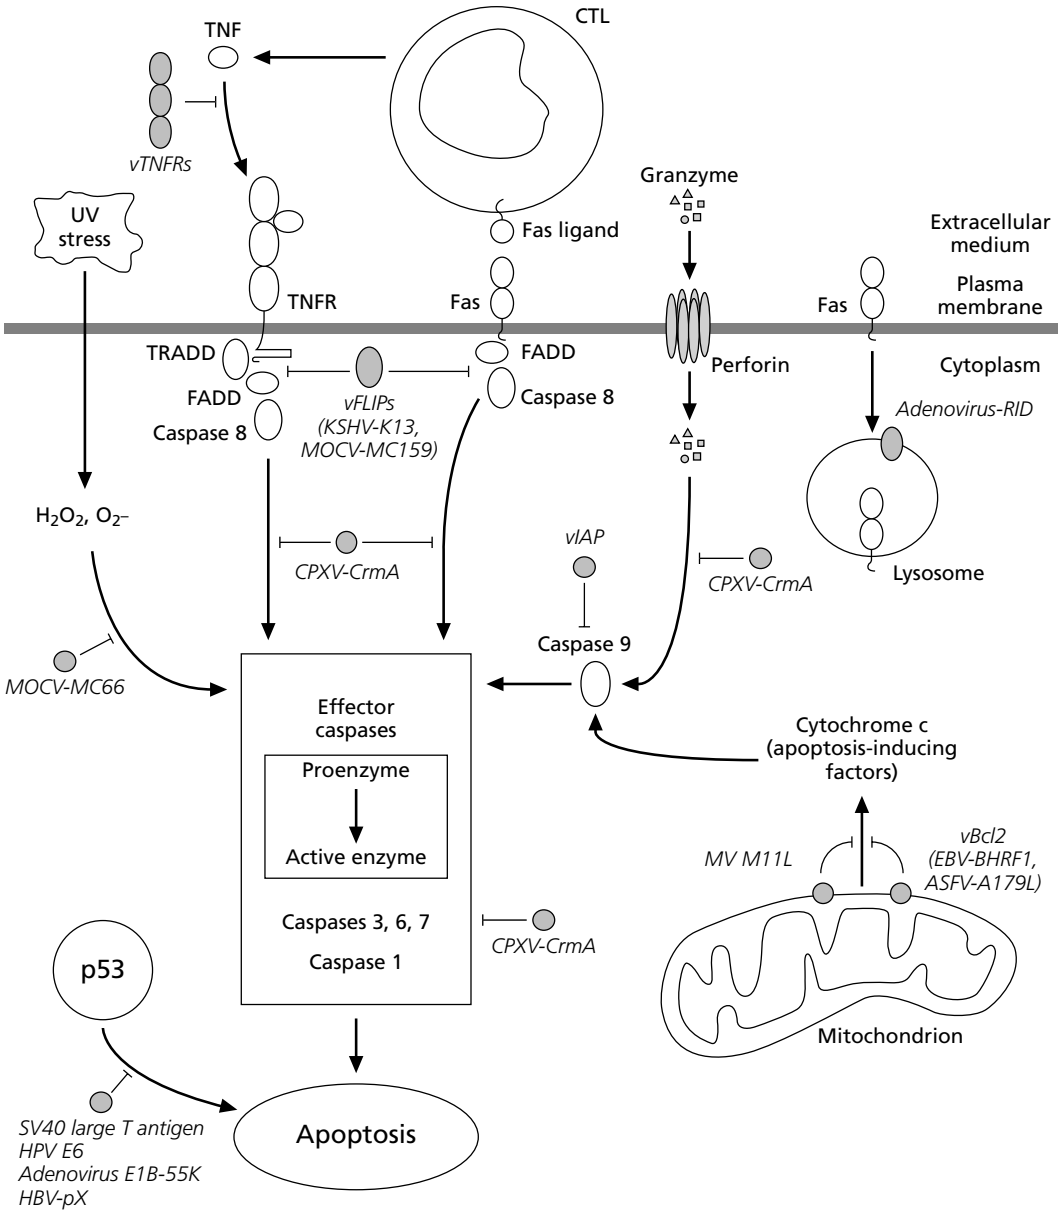

Figure 6 *Viral inhibition of apoptosis*

Inhibition of caspases

Caspases are proteolytic enzymes that are critical for the induction of apoptosis, and many viral proteins have been described to inhibit their activity (Figure 6). The CrmA protein encoded by CPXV, VACV and other poxviruses blocks caspase 1 and caspase 8, which play critical roles in major pro-apoptotic pathways, and prevents apoptosis initiated by several stimuli including TNF, FasL, and granzyme B (Miura et al. 1995; Talley et al. 1995; Tewari et al. 1995). In addition, CrmA inhibits the proteolytic maturation of IL-1β and, presumably, IL-18, cytokines that are cleaved by caspase 1 (Ray et al. 1992). The enzymatic activity of caspases is regulated by a family of inhibitor of apoptosis proteins (IAP) that were originally identified in baculoviruses, a family of insect viruses (Clem and Miller 1994). IAP homologues are not frequently found in mammalian viruses, with the exception of ASFV (Neilan et al. 1993). The adenovirus E3-14.7K protein inhibits caspase 8 through interactions with a small GTPase and dynein (Lukashok et al. 2000).

Inhibition of mitochondrial pathways of caspase activation

Apoptosis can also be controlled at the level of mitochondria, as a result of loss of extracellular viral signals or by signals affecting the cell cycle (Rathmell and Thompson 2002). The release of cytochrome c, which

resides in the space between the inner and outer membranes of the mitochondria, oligomerizes APAF1 and recruits pro-caspase 9 forming a protein complex known as the apoptosome and activates caspase 9 leading to apoptosis. Bcl2 is a cellular protein that resides in the outer mitochondrial membrane and inhibits the release of cytochrome c from the mitochondria. A number of viruses encode Bcl-2 homologues to prevent the induction of apoptosis, including adenovirus, ASFV, and the gammaherpesviruses EBV, KSHV and MHV-68 (Afonso et al. 1996; Cheng et al. 1997; Gangappa et al. 2002; Henderson et al. 1993; Sarid et al. 1997) (Figure 6). The HCMV protein UL37 shares no sequence similarity to Bcl-2 but resides in the mitochondria and is functionally similar to Bcl-2 (Goldmacher et al. 1999). Recently, the MYXV protein M11L has been shown to closely associate with a component of the mitochondrial permeability transition pore and to prevent apoptosis (Everett et al. 2002). A related protection of mitochondrial membrane potential has also been observed with VACV, but the viral protein responsible for it has not been identified (Wasilenko et al. 2001).

Other anti-apoptotic mechanisms

The tumor suppressor p53 limits cell proliferation by inducing apoptosis or cell cycle arrest. p53 stimulates transcription of genes involved in apoptotic pathways, and viruses can disrupt apoptosis by inactivating p53 (Figure 6). The simian virus 40 (SV40) large T antigen sequesters p53 in an inactive complex (Lane and Crawford 1979; Linzer and Levine 1979). The human papillomavirus (HPV) E6 protein and adenovirus E1B-55K protein promote ubiquitylation and degradation of p53 by different mechanisms (Scheffner et al. 1990; Steegenga et al. 1998; Werness et al. 1990). The hepatitis B virus (HBV) pX protein binds p53 and inhibits p53-mediated apoptosis (Wang et al. 1995). An alternative mechanism is represented by the glutathione superoxide MC66 encoded by MOCV which protects infected cells from peroxide radicals and ultraviolet radiation, and perhaps from peroxide radicals induced by TNF, macrophages, and neutrophils (Shisler et al. 1998).

CONCLUSIONS AND FUTURE PERSPECTIVES

In the past, viral immunology studies have characterized the host mechanisms to prevent and eliminate viral infections. The ability of many viruses to evade the host immune response by antigenic variation was shown many years ago. However, it is in the last ten years that we have become more aware of the many viral proteins that have evolved to block host specific mechanisms of antiviral immunity. There are numerous viral proteins without an ascribed function and it is likely that many of these proteins encode new viral immune evasion strategies, which may only be evident in the infected host. The fact that we have not identified these viral functions may reflect our limited knowledge of the molecular mechanisms of immunity.

The reasons why a virus blocks a particular immune mechanism is not clear, and may depend on the replication and transmission mechanisms adopted by the virus. Many questions need to be resolved in the future. We need to determine which viral genes are required for the initial steps of the infection or for efficient transmission to another host in the presence of an active immune system. The apparent complexity and redundancy of these viral proteins may only be understood in the context of viral infection in the host. The lack of good animal models of infection for many viruses is limiting our understanding of the function of viral immune evasion strategies in vivo.

A better knowledge of the interaction of viruses with the host defense mechanisms will help us to understand the mechanisms of viral pathogenesis. Very often, the pathology observed in viral infections is not due to viral replication but a consequence of the immune and inflammatory responses to infection that may cause damage in the host. Moreover, some viral proteins may directly cause the pathological effects during infection. Some human inflammatory and autoimmune diseases are the result of an uncontrolled production of immune mediators such as TNF and IL-1 that constantly activate the immune response. We are finding examples of viral proteins that may enhance these immunopathological responses in the infected host.

The deletion of viral immune evasion proteins from the viral genome causes viral attenuation in most cases due to increased host defenses. However, enhanced viral virulence has been observed in VACV and CPXV when some of these viral functions have been deleted from the genome. These include the soluble vIL-1βR, IMP, and the 35 kDa vCKBP (Alcami and Smith 1992; Miller et al. 1997; Reading et al. 2003). These surprising observations suggest that the function of some of the viral immune evasion proteins is not to promote viral replication but to 'protect' the host from the detrimental effects of an over-reactive immune system, mediated in these examples by IL-1β, complement or chemokines, respectively. An enhanced host survival will be beneficial since the virus fully depends on the host for its replication. The complex interaction of each virus with the immune system is unique, and a better understanding of this interaction will lead to new strategies to control viral replication and the design of more efficient viral vaccines.

The fact that viruses have co-existed with their hosts during evolution and are able to survive in the presence of potent host defense mechanisms suggests that viruses know the mechanisms of immunity better than us. Viruses point at those molecules that play a critical role

in defense against pathogens, one of the primary aims of the immune system, and thus viruses offer us a unique opportunity to identify basic mechanisms of immunity. Moreover, viruses may help us to understand the function of some of the large number of human genes recently identified in the human genome. The study of viral mechanisms of immune evasion is fascinating and will increase our understanding of the complex interaction of viruses with the host immune system.

Viral oncogenicity

JAMES C. NEIL AND JOHN A. WYKE

Introduction	1	Principles of the management of virus-associated cancer	18
The pathogenesis of tumor viruses	5	Conclusions	21
Implication of viruses in the etiology of cancer	12	References	21

INTRODUCTION

A brief history of tumor virology

The incidence of tumors in animals and humans often shows geographical variation. This clustering sometimes reflects genetic differences in the populations at risk but more often results from environmental factors that vary between populations. Features of the environment that enhance the risk of tumor development (i.e. carcinogens) comprise physical factors (such as ultraviolet and other irradiation that impinges on and penetrates the body), chemical factors (ingested or contaminating the body surface), and infectious agents. Of the last, the most important are viruses. Viruses that produce tumors in animals have been known since the early 1900s, but it is only in recent decades that they have excited great interest. The reasons for this are twofold.

First, as diverse viruses were increasingly implicated as causes of cancer in animals of all vertebrate classes, it was hoped that they might also be important in the etiology of human neoplasia. This concept was attractive, not least because it suggested that, if the causative organisms could be identified and characterized, the incidence of cancer might be reduced by the prophylactic measures so successful against other infectious agents. The development of a tumor is usually a rare outcome of virus infection but it has nevertheless been estimated that up to 20 percent of human tumors have a viral risk factor (zur Hausen 1991) (Figure 1). Only one family of RNA-containing viruses, the retroviruses, has well-established oncogenic members (Table 1), but representatives of all the major subdivisions of DNA-containing viruses (except the parvoviruses) in vertebrates have been implicated in neoplasia. Examples are given in Tables 2 and 3, p. 3, but, because all these agents receive attention elsewhere in this volume, this chapter will concentrate on general principles rather than specific details.

The second reason for an interest in viruses was their promise as tools for studying the basic mechanisms underlying neoplastic change. This idea rested on several earlier developments in laboratory research. Inbreeding of laboratory animals produced some strains with high incidence of various virus-associated neoplasms. In addition, inbred strains permitted transplantation studies, which demonstrated that a single donor cell could produce a tumor in the recipient animal. This finding focused attention on changes that occurred at a subcellular level and provided the rationale for studying oncogenesis in vitro rather than in the whole animal. This switch in emphasis was facilitated by the development of tissue culture techniques and, at the same time, it was found that tissue culture was an ideal way to measure the cytopathic effects of viruses, so that animal virologists could adopt the quantitative approach developed in studies on bacteriophages.

A correlation soon emerged between the ability of viruses readily to cause solid mesenchymal tumors in animals and their induction of morphological transformation of cultured cells (Figure 2, p. 4). This finding had important implications, not widely appreciated at the time. Following Theodor Boveri's proposals in 1914, the notion that tumors were clones of cells whose altered

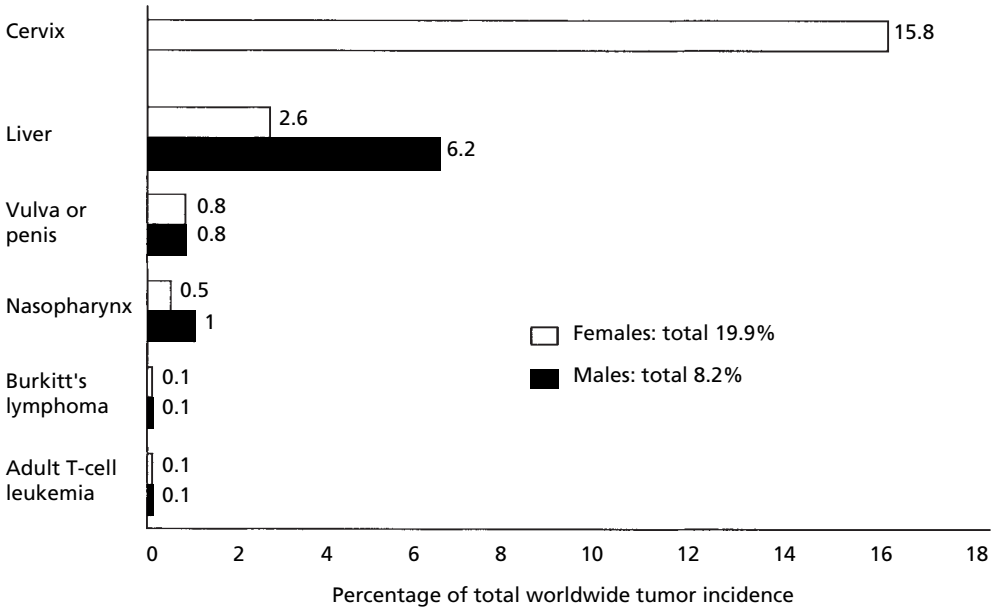

Figure 1 *Incidence of human tumors in which virus infection is a risk factor. The viruses most strongly implicated are papillomaviruses – tumors of cervix and external genitalia (Papillomaviruses); HBV – primary liver tumors (Hepatitis delta virus); EBV – Burkitt's lymphoma and nasopharyngeal carcinoma (Gamma herpesviruses: Epstein–Barr virus); and human T-cell leukemia viruses – adult T-cell leukaemia (Retroviruses and associated diseases in humans). (Modified, with permission, from zur Hausen 1986.) Note that these estimates do not include recent changes in cancer incidence due to HIV infection (Retroviruses and associated diseases in humans and 60, Human immunodeficiency virus).*

properties result from accumulated mutations was accepted by many scientists (Baltzer 1964). However, before molecular genetic technology was developed, they could not conceive ways of identifying, among the thousands of genes in every somatic cell, the putative subsets that were mutated. Tumor viruses seemed to offer a way round this impasse. Some of them possessed only a few genes among which, it was argued, were those that

Table 1 *Some RNA viruses implicated in cancers of animals and humans*

Virus classification	Virus	Associated tumors	Other risk factors
Retroviridae			
Alpharetroviruses	ALVs; Rous sarcoma virus	Various sarcomas, some carcinomas, lymphomas, and leukemias	Genetic susceptibility affecting virus penetration replication and spread
Betaretroviruses	MMTV	Mammary adenocarcinomas, T-cell lymphoma	Pregnancy (altered hormone levels)
	JSRV	Pulmonary adenoma	. . .
	Mason–Pfizer monkey virus	Fibrosarcomas	. . .
Gammaretroviruses	MLV, murine sarcoma virus	Lymphomas, leukemias, and sarcomas	Genetic susceptibility to viral infection and spread
	Reticuloendotheliosis virus (avian)	Lymphomas and leukemias	. . .
	FeLV, feline sarcoma virus	Lymphosarcomas (mainly T cell), myeloid leukemias, fibrosarcomas	Age at exposure, immunosuppression
Deltaretroviruses	HTLV-I, HTLV-II	Adult T-cell leukemia	. . .
	BLV	Lymphosarcoma (B cell)	. . .
Lentiviruses	HIV	B lymphomas, Kaposi's sarcoma	EBV, KSHV
	Simian immunodeficiency virus	B lymphomas	Simian herpesvirus
	Feline immunodeficiency virus	B lymphomas	FeLV
Flaviviridae	HCV	Hepatocellular carcinoma	. . .

ALV, avian leukosis virus; BLV, bovine leukemia virus; BPV, bovine papillomavirus; EBV, Epstein–Barr virus; FeLV, feline leukemia virus; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HPV, human papilloma virus; HTLV, human T-cell leukemia virus; HVS, herpesvirus saimiri; JSRV, jaagsiekte sheep retrovirus; MLV, murine leukemia virus; MMTV, mouse mammary tumor virus; SIV, simian immunodeficiency virus; WHV, woodchuck hepatitis virus.

Table 2 *Some oncogenic small DNA viruses of animals and humans*

Virus family	Virus	Host of origin	Associated tumors	Other risk factors
Hepadnaviridae	Hepatitis B group	Humans, apes, rodents, ducks	Primary hepatocellular carcinoma	In humans: alcohol, smoking, fungal toxins, other viruses
Papovaviridae	Polyoma	Mouse	Various carcinomas and sarcomas	. . .
	SV40	Monkey	Sarcomas, mesothelioma (in rodents, man?)	. . .
	BK and JC	Human	None in humans; neural tumors in rodents and monkeys	. . .
	Papilloma	Human	Genital, laryngeal and skin warts; may progress to:	. . .
			Cervical carcinoma	Smoking, herpes simplex viruses, immunosuppression
			Laryngeal carcinoma	X-irradiation, smoking
			Skin carcinoma	Sunlight, genetic disorders
		Cattle	Genital, alimentary, skin warts; may progress to:	. . .
			Alimentary carcinoma	Carcinogens and immunosuppressants in bracken fern
			Skin carcinoma	Sunlight, genetic predisposition (lack of pigmentation)
		Other mammals	Papillomas; may progress to carcinomas	Experimentally, carcinogens such as methylcholanthrene

transformed cells in vitro and induced tumors in vivo. Identification of these viral cancer genes (oncogenes) should help define the molecular basis of cancer, because they might have functional analogues among the cellular genes required for neoplasia. Although naive in hindsight, this concept proved correct for the retroviruses used widely by laboratory workers. Indeed, for the retroviruses, its significance exceeded expectations, for in many cases the viral oncogenes were descended from cellular cognates, the proto-oncogenes. These, in turn, have been convincingly implicated in the genesis of a range of animal and human tumors of both viral and nonviral etiology. The

Table 3 *Some oncogenic large DNA viruses of animals and humans*

Virus family	Virus	Host of origin	Associated tumors	Other risk factors
Adenoviridae	Types 2, 5, 12	Human	None in humans; sarcomas in hamsters	. . .
Herpesviridae	Frog herpesvirus	Leopard frog	Adenocarcinomas	Ambient temperature
	Marek's disease	Fowl	Neurolymphomatosis (T cell)	Genetic predisposition, MHC and non-MHC loci
	Herpesvirus ateles and saimiri	Monkeys	Lymphoma, leukemia	. . .
	EBV	Human	Burkitt's lymphoma, Hodgkin's disease, immunoblastic lymphoma	Malaria, HIV, immunodeficiency
			Nasopharyngeal carcinoma	Salted fish in infancy, HLA type
	Herpes simplex (types 1and 2)	Human	Cervical neoplasia	Papillomaviruses, smoking, immunodeficiency
	Cytomegalovirus	Human	Cervical neoplasia	Immunodeficiency, HLA type
	Kaposi's sarcoma herpesvirus (KSHV/HHV8)	Human	Kaposi's sarcoma, primary effusion lymphoma/ Castleman's disease	HIV
Poxviridae	Shope fibroma	Rabbit	Fibroma	. . .
	Yaba monkey tumor virus	Monkey	Nodular fibromatous hyperplasia	Not relevant; progressive tumors never develop
	Molluscum contagiosum	Human	Nodular epidermal hyperplasia	. . .

Note that the colony is flat and the cells are lined in parallel array.* **(b)** *The same cell line after transformation by* Polyomavirus. *The cells are piled on one another and lack orientation.*

DNA tumor viruses have also provided vital insights into the cancer process because their oncogenes encode proteins that interfere with cellular checkpoint controls of proliferation and survival which have in a similar fashion proved to be of general relevance in human cancer.

These concepts gave rise to a large amount of work, reviewed elsewhere (Bishop 1991; Vogelstein and Kinzler 1992). This chapter summarizes in turn the two broad divisions of tumor virology:

1. studies on the molecular mechanisms of virus-induced neoplasia
2. attempts to implicate viruses in the aetiology of cancer.

These divisions, however, share concepts and techniques, and are increasingly considered together (Minson et al. 1994). Such a unitary approach is particularly important when attempting to combat virus-associated cancer, as outlined in the third part of this chapter.

Paradoxically, the tumor viruses themselves are now being developed as part of our anticancer armory.

Cancer – a disorder of cellular controls

The development of a fertilized egg into a multicellular organism and the subsequent maintenance of its form and function require complex controls over cell proliferation and cell death, and the expression of differentiated cell functions. These attributes of cells result from an interplay between stimuli from outside the cell and its current program of activity. Many of these stimuli are mediated by chemical signals classified according to their origin; endocrine signals originate from distant cells, paracrine signals from cells in the neighborhood of the recipient, and autocrine signals from the recipient cell itself. Whatever their origin and consequence, these signals have an effect only if the recipient cell has appropriate cell surface or internal receptors for the signal, an appropriate machinery of second messengers to process it and the metabolic capacity to respond.

Perturbations in these controls can lead to local increases in tissue mass. These may be the response of a normal cell to abnormal stimuli, leading to cell hypertrophy or, if the cells can multiply, to hyperplasia. On the other hand, the cells themselves may be altered, so their growth and behavior are no longer controlled in the same way as their normal counterparts and they become neoplastic. We might expect neoplasia to result from a change in any of the components of the system by which the cell responds to external signals, and there is now considerable evidence that in neoplastic cells mutations exist that change the function of various components in the signaling pathway controlling cell proliferation. As we shall see, viral oncogenes frequently act to stimulate growth in this way.

However, the oncogenes represent only one facet of the genetic basis of cancer. The requirement for recessive mutations in cancer was long suspected, both from the occurrence of inherited cancer syndromes (Knudson 1993) and from classic in vitro cell fusion studies where the transformed phenotype was often found to be extinguished in hybrid cells (Harris 1985). It was suspected that the genes underlying these phenomena might play a role in commitment to terminal differentiation, with loss of function leading to a block at an immature, highly proliferative stage. Although there is evidence to support this hypothesis for a number of genes, the most widely implicated tumor suppressor genes appear to play quite different roles in controlling cell cycle progression ('gatekeepers') or in maintaining the integrity of the genome ('caretakers') (Shields and Harris 2000). Given the fundamental nature of these roles, the discovery that the archetypal tumor suppressor, p53, is dispensable for normal development was a surprise to the field. Mice lacking functional p53 are ostensibly normal, but are prone to develop tumors, particularly lymphomas (Donehower et al. 1992). In its normal physiological role, p53 orchestrates cellular responses to genotoxic damage; induction of p53 leads to cell cycle arrest and allows repair synthesis to occur. Whilst this phenomenon is a partial explanation for the protective role of p53, there is another important facet to the story. Cells in which p53 is induced may also undergo programmed cell death or apoptosis as a consequence (Yonish-Rouach et al. 1991). This cell suicide mechanism, which plays vital roles in normal development and morphogenesis, also serves as a brake to cancer development. For cancer to develop, it seems that cells must acquire mutations which block cell death as well as those which drive cellular proliferation (Liebermann et al. 1995).

In practice, the simple binary classification of cancer genes as oncogenes or tumor suppressors is no longer tenable as some genes display facets of both, with gain or loss of function of a single gene contributing to tumor development in different cellular contexts (Lee and Farnham 2000; Wotton et al. 2002). The p53 protein itself is functionally complex, as some mutant forms act as dominant negative inhibitors of the wild-type counterpart, hence acquiring oncogene-like properties (Vogelstein and Kinzler 1992). Also, certain oncogenes (e.g. c-*myc*) actually induce growth stasis or apoptosis instead of proliferation when overexpressed in a cellular environment unfavorable for growth (Evan et al. 1992). Such mechanisms serve to protect multicellular organisms from cancers and explain the need for multiple genetic events to transform normal cells to full malignancy.

THE PATHOGENESIS OF TUMOR VIRUSES

Reasoning from first principles, we can envisage many ways by which features of virus infection might favor the development of tumors. The interactions between viruses and their hosts are such that it is clear that most of these mechanisms exist in one or another naturally occurring cancer. Indeed, the genesis of a given neoplasm may be influenced by more than one mechanism, because they are not mutually exclusive.

Direct oncogenic mechanisms

A first major category of pathogenic mechanism is direct or intrinsic, in which the tumor cells, or at least their ancestral lineage, are infected by the causative virus. Although this mechanism was presumed to be involved in studies of tumor viruses in vitro, only one aspect of it was useful to the experimenter – that in which all or part of the virus genome persisted in the tumor lineage. Genome persistence provides a marker that pinpoints crucial events in tumorigenesis, either because a specific portion of the virus is always present or because the

genome is inserted in a specific region of the host chromosome DNA.

The consistent presence of a viral gene, either free in the cell or integrated randomly in host DNA, suggests that it directly contributes to the neoplastic phenotype. These viral oncogene functions can supersede those of the cell and invariably mediate either oncogenicity by the virus or its presumed counterpart in vitro, cell transformation (see Figure 2).

THE RETROVIRAL ONCOGENES

The oncogenes of most retroviruses play no part in virus replication. Indeed, many replace portions of viral replicative genes in the virus genome. These oncogenes (v-*onc*) are related to sequences in normal host cells from which they are believed to evolve after capture (transduction) of the cellular gene, known as a proto-oncogene (c-*onc*), during some ancestral infection (Table 4). Such transduction is observed in certain naturally occurring tumors; however, because it is sporadic, and because oncogene transduction appears to confer no advantage on the virus for transmission (Onions et al. 1987), it appears to represent an evolutionary dead-end. However, for the 'simple' retroviruses such as the alpha and gammaretroviruses, de novo oncogene transduction can in some circumstances be observed in a high proportion of tumors (Neil et al. 1984; Miles and Robinson 1985; Tsatsanis et al. 1994). Transduction has major implications for understanding the mechanism of neoplasia because, if cell proto-oncogenes can mediate neoplasia when incorporated within a virus genome, they might also be able to do so in other circumstances. A considerable body of evidence now suggests that this is the case, some of the earliest data coming from work on the mode of tumor virus pathogenesis described next.

Since the first glimpses of oncogenes in rapidly transforming retroviruses, it has been apparent that their products can be demonstrated in many different cellular

Table 4 *Examples of genes transduced by retroviruses in cancer*

Viral oncogene	Location, structural features of gene product	Normal function of host-cell gene[a]	Transducing virus[b]	Associated tumors

sites; their functions, where elucidated, identify these as components of pathways of growth control signaling and response. The captured versions of these cellular genes are released from normal transcriptional and translation controls when expressed as part of the viral genome. Furthermore, if the viral version of the gene is truncated or mutated, functional controls may be lost. Thus, retroviral oncogenes are in some cases altered forms of growth factors (e.g. v-*sis*), transmembrane growth factor receptors (some of which are protein tyrosine kinases such as v-*erb*-B) or 'G proteins' that couple ligand–receptor interactions to intracellular signaling events (e.g. the *ras* gene family). Others are second messengers, such as the intracellular protein tyrosine kinases and serine–threonine kinases. The oncogenes whose products are located in the nucleus can affect DNA synthesis or, more probably, gene expression; examples are v-*jun* and v-*fos*, which encode nuclear proteins that assemble as heterodimers to form a well characterized transcription factor complex (AP-1). It is easy to appreciate that mutations altering the expression of one of these genes, or their products, might short-circuit normal cell controls and lead to unregulated growth and behavior. However, it remains a major challenge to understand the detailed mechanism of many of these perturbations. For a comprehensive listing of the known oncogenes and their properties, the reader is referred elsewhere (Hesketh 1997).

The leukemogenic deltaretroviruses bovine leukemia virus (BLV), human T-cell leukemia viruses (HTLV) (HTLV-I, HTLV-II), and simian T-cell leukemia virus (STLV-I) form a discrete subgroup where a normal constituent of the viral genome is implicated in transformation. They contain a region, called p*X*, which encodes Tax and Rex, along with a series of minor gene products. The Tax protein is the most clearly implicated in the process of in vitro transformation by these viruses. It acts on the long terminal repeat (LTR) of the integrated provirus, usually to increase viral transcription, through interaction with cellular transcription factors (Figure 3); as a result of this activity, it can also modulate the transcription of cellular genes (see Retroviruses and associated diseases in humans). However, it should be noted that tumors are rare and late consequence of HTLV infection, and that most tumors have downregulated the expression of Tax and other viral proteins (Matsuoka 2003). In this context, the deltaretroviruses must be considered as initiating factors, with largely unknown mutations to cellular genes playing a rate-limiting role in the leukemogenic process.

A further example of a retroviral product that plays a direct role in oncogenesis is provided by the Friend spleen focus-forming virus (SFFV), an unusual defective isolate encoding a truncated envelope protein that binds to and activates the erythropoietin receptor in the absence of its natural ligand (Ruscetti 1999). Another is the recently characterized jaagsiekte sheep retrovirus (JSRV), a betaretrovirus which has been shown to be the causal agent of the sporadic epithelial tumor, ovine pulmonary adenomatosis. Transformation of fibroblast cells in vitro is mediated by the viral envelope gene, although it as yet unclear whether this activity is sufficient to explain the malignant potential of JSRV (Chow et al. 2003).

THE ONCOGENES OF DNA TUMOR VIRUSES

The observation that SV40 T antigen binds tightly to a cellular protein, p53 (Lane and Crawford 1979; Linzer and Levine 1979) was the first step towards the elucidation of a transformation mechanism common to many of the DNA tumor viruses. Binding results in the inactivation or degradation of the cellular target protein. Furthermore, T antigen also binds and inactivates a second tumor suppressor, pRb. The p53 and Rb pathways are common targets for many of the DNA virus oncoproteins, although the mechanisms by which their functions are subverted are varied and may be direct or indirect (see Table 5, p. 9).

The transforming genes of SV40 and the other small DNA viruses of the papovavirus group bear no close relationship to cellular gene products, but interact with key factors controlling host cell replication to create a permissive environment for the virus to replicate its own genome. If the viral replication cycle fails to proceed past the expression of these early gene products, the result is a persistently infected, transformed cell. In this abortive mode of replication, the host cell is induced to multiply abnormally and will present few viral antigens to the host immune system, with obvious advantages to the virus in establishing latent or persistent infection. There are other mechanisms by which DNA tumor virus oncogenes can interfere with cell growth regulation, as shown by polyomavirus middle T antigen which interacts in subtle ways to activate nonreceptor tyrosine kinases at the plasma membrane (Kiefer et al. 1994). Moreover, polyomavirus small t antigen interferes with p53 indirectly by uncoupling responses to its upstream activator, Arf (Lomax and Fried 2001). Also, cell lifespan, and hence susceptibility to transformation, can be increased by activation of telomerase as reported for human papillomavirus (HPV) E6 (Klingelhutz et al. 1996). For hepatitis B virus (HBV), analysis of viral oncogenic functions has been hampered by the lack of tractable in vitro systems. However, both p*X* and the large envelope protein preS can transactivate cellular genes (Rossner 1992), while the pX protein has been reported to bind and inactivate p53 (Truant et al. 1995).

While transformation by the papovaviruses is a consequence of abortive infection, the oncogenic herpesviruses have evolved latent infection as an essential feature of the normal life cycle. In the minimal state, the virus expresses only those functions necessary to maintain and ensure replication of its episomal DNA genome

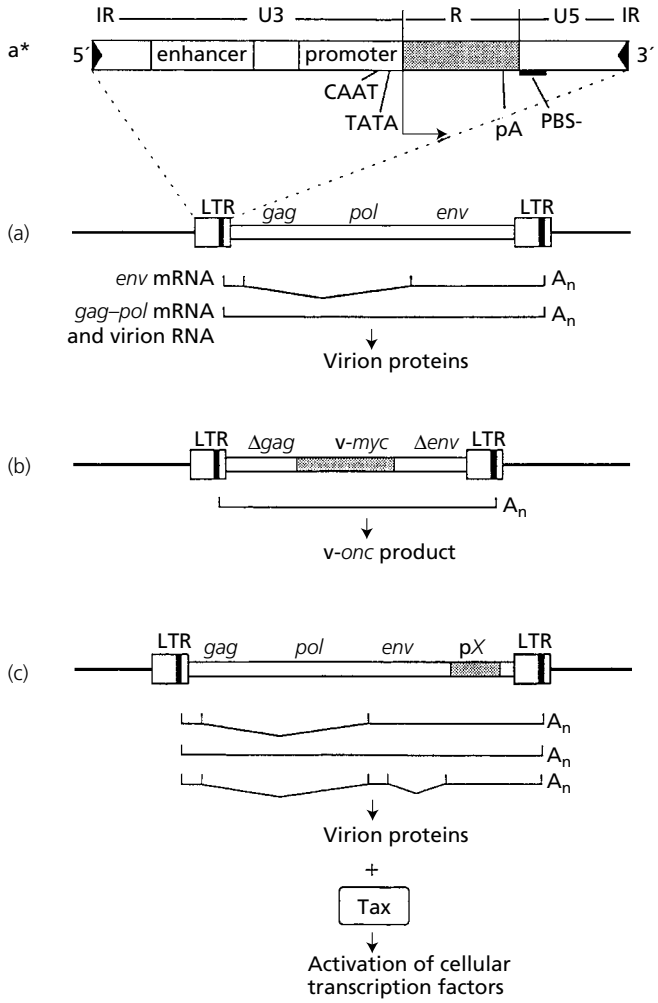

Figure 3 *Retroviruses and associated diseases in humans, considers retroviruses at length. This figure and Figure 4 give only enough detail to appreciate their pathogenesis.* **(a*)** *Detail of a typical retroviral LTR. Each LTR resembles an insertion sequence, having an inverted repeat (IR) at its extremities. A direct repeat (R) derives from either end of the virion RNA, with a cap site at its 5′ end (large arrow) and a polyadenylation signal (pA) close to its 3′ end. The 3′ boundary is marked by a primer binding site (PBS) to which is bound the tRNA primer for reverse transcription of virion RNA. The remainder of the LTR comprises U3 and U5 regions, derived respectively from the 3′ and 5′ ends of viral RNA. U3 contains a promoter region, with characteristic 'CAAT' and 'TATA' boxes that regulate proviral transcription. Upstream (5′) to the promoter is an enhancer with a nonpolar stimulatory effect on gene expression.* **(a)** *A retroviral provirus (boxes) integrated in cell DNA (thick line). LTRs flank and control the expression of coding regions that comprise, in replication-competent retroviruses, at least three genes,* gag, pol, *and* env, *expressed through unspliced or spliced polyadenylated mRNAs.* **(b)** *A retroviral provirus bearing a viral oncogene (v-*onc*), in this case the v-*myc *in the avian myelocytomatosis virus 29. The oncogene region of this virus (pX) encodes Tax, Rex, and a series of other minor products (p30, p12), which have no known cellular counterparts. Tax interacts with cellular transcription factors to transactivate a range of cellular genes, including IL-2 and its receptor.*

in the host cell. For the best characterized oncogenic herpesvirus, Epstein–Barr virus (EBV), a subset of six viral gene products has been implicated in the efficient immortalization of B cells, including a series of nuclear proteins (EBNAs) and two membrane proteins (LMP1 and 2), and the same gene products are expressed in EBV-positive immunoblastic lymphomas which arise in immunosuppressed transplant recipients and patients with the acquired immunodeficiency syndrome (AIDS). A key effector of transformation is LMP1 that appears to mimic the action of a constitutively active tumor necrosis factor (TNF) family receptor (Eliopoulos and Young 2001). A more limited subset of EBV proteins (EBNA1, LMP1 and -2) is expressed in nasopharyngeal carcinoma cells, while Burkitt's lymphoma cells express only EBNA1 (Rickinson 1994).

The human adenoviruses are oncogenic only in rodents, but have served as important models of cell transformation. Again, their major effectors (E1A, E1B, E4Orf6) appear to operate by similar principles, by

Table 5 *Selected DNA tumor virus oncogenes and mechanisms of action*

Virus	Effector	Target/mechanism
SV40	Large T antigen	Binds, inactivates p53, Rb
Polyoma	Middle T antigen	Binds activates src family kinases
	Small T antigen	Inhibits Arf/p53 activation
HPV	E6	p53 binding, degradation
	E7	Rb binding
BPV	E6	p53 binding
HBV	pX	Binds inactivates p53
Adenovirus	E1A	Rb
	E1B	Bak, Bax binding; inhibition of apoptosis

binding to and inactivating p53 (Shen and White 2001; Tauber and Dobner 2001) and Rb (Gallimore and Turnell 2001) or inhibiting their downstream effectors (Shen and White 2001).

The large DNA tumor viruses encode many products that affect growth and survival of the infected cell, and others that allow infected cells to evade the host immune response. These include homologues of cellular genes encoding cytokines as well as regulators of apoptosis and cell-cycle progression. Many of these products have the theoretical potential to contribute to neoplastic transformation, but the term 'oncogene' is usually reserved for those products that have been implicated directly in the initiation or maintenance of oncogenic transformation. Despite their potency in various in vitro transformation assays, most DNA tumor viruses are weakly oncogenic, particularly in their natural hosts. This may be explained in part by the efficiency of the host immune response in controlling virus replication and destroying potential tumor cells that express virus-coded cell surface antigens or T-cell epitopes. However, immunosuppression reveals the malignant potential of these infections. EBV-induced malignancies are a significant complication in patients undergoing organ transplant or in the context of human immunodeficiency virus (HIV)-induced immunosuppression (Holmes and Sokol 2002). In a similar fashion, the indirect effects of HIV potentiate the carcinogenic effects of HPV infection (Hawes et al. 2003) and have increased the prevalence of Kaposi's sarcoma to the point where it is now one of the most common virus-associated malignancies (Boshoff and Weiss 2001).

A summary of the targets and mechanisms of action of DNA tumor virus oncoproteins is given in Table 5. Note, however, that these are in general a small subset of the binding interactions and effects of these multifunctional viral proteins.

INSERTIONAL MUTAGENESIS

Many retroviruses lack an oncogene but induce clonal tumors in which their genome is integrated as a DNA provirus in a specific region of the host chromosome (Figure 4). This insertion is mutagenic, so it changes the sequence of DNA in that region, and can have either of two results: activation of a gene or its ablation. In most cases proviral insertion activates a nearby gene, either by qualitative alteration or by augmentation of its expression (Peters 1990; Kung et al. 1991). In some cases the activated gene proves to be the cellular counterpart of a known retrovirus oncogene. Thus, B-cell lymphomas induced by avian leukosis virus (ALV) and T-cell lymphosarcoma induced by feline leukemia virus (FeLV) often contain a c-*myc* gene activated by insertional mutagenesis. In ALV-induced erythroleukemia, on the other hand, it is the c-*erb*-B proto-oncogene that is activated. These findings support a role for proto-oncogenes in neoplasia, and in the latter case also appear to represent an intermediate stage in the process of oncogene transduction (Nilsen et al. 1985).

By extrapolation from the observed activation of known proto-oncogenes by proviral insertion, it can be argued that, when an inserted virus consistently integrates into a limited region of the host genome in a series of tumors, the affected region harbors a putative oncogene. In this way a large number of loci have been identified, of which the activation is characteristic of certain virus-induced tumors; the available evidence as to the nature of these loci strongly supports the concept that their activation is relevant to neoplasia.

Although the first example of insertional mutagenesis came from avian lymphomas (Neel et al. 1981), much recent work to identify new oncogenes has been in the laboratory mouse. Moreover, the use of this facet of retroviral oncogenesis as a gene discovery tool by 'tagging' of target genes has enjoyed a renaissance since the completion of the draft human and mouse genome sequences (Neil and Cameron 2002). The target gene at a common insertion site can in some cases be difficult to determine, not least because retroviral *cis*-activation of target genes can in some cases operate over a great distance (up to 300 kb) (Lazo et al. 1990; Hanlon et al. 2003).

The strategy of retroviral tagging is complemented by the parallel development of techniques for the manipulation of the mouse genome. Thus, the introduction of

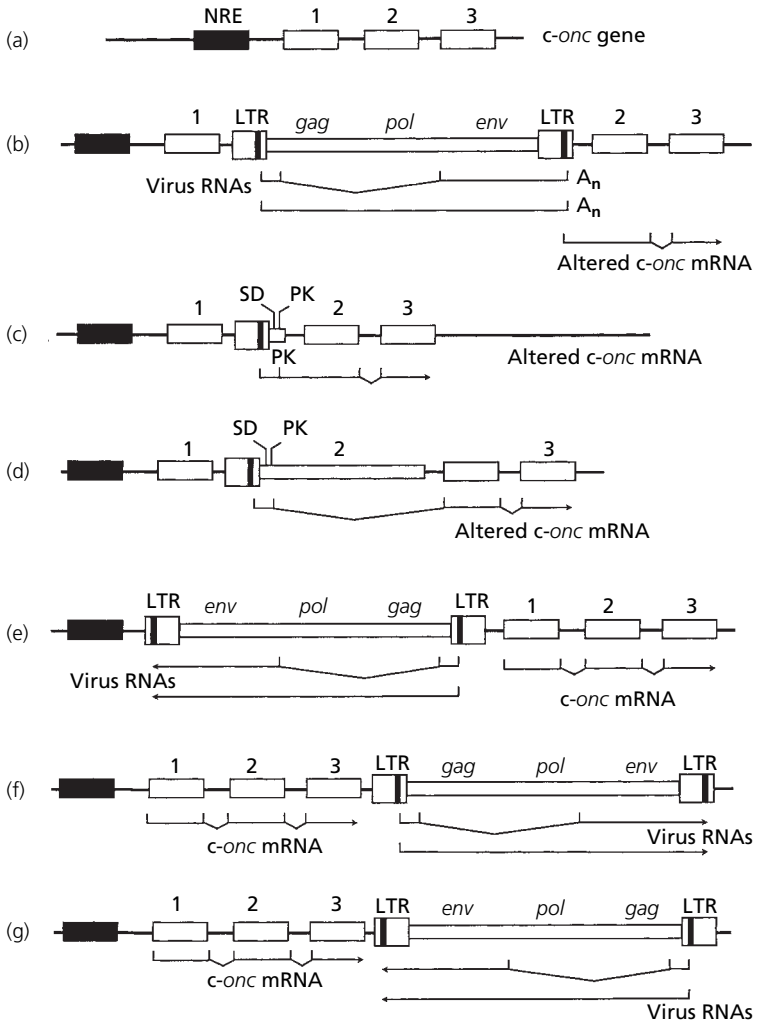

Figure 4 *Modes of insertional mutagenesis. The examples given show insertional mutagenesis by a retroviral provirus, but WHV (Buendia 1994) and others may have comparable effects.* **(a)** *Diagram of a proto-oncogene (*c-onc*) comprising three exons (open boxes), the first of which is largely noncoding, and an upstream negative regulatory element (NRE) (closed box), which helps to ensure that the gene is often poorly transcribed.* **(b)** *Insertion of a provirus between exons 1 and 2 of the* c-onc *gene. Expression of* c-onc *is elevated by 'promoter insertion,' regulatory elements in the 3′ LTR driving transcription of a viral* c-onc *hybrid message.* **(c)** *Insertion of a truncated provirus, with* c-onc *transcription initiating in the 5′ LTR. In this instance the transcript is not spliced at the donor site (SD) for generating subgenomic viral mRNA, so it includes the sequence (PK) 3′ to SD that permits packaging of the RNA into virions. This altered* c-onc *mRNA may thus be incorporated in an infectious virion, and infection leading to reverse transcription and genetic recombination with another viral RNA could generate a virus containing a transduced* onc *gene.* **(d)** *Another example of promoter insertion by a truncated provirus. In this case the packaging signal is spliced out of the mRNA so, like subgenomic viral mRNA, it is unlikely to be incorporated into virions.* **(e)** *Proviral insertion 5′ to* c-onc*, but in the opposite transcriptional orientation, precluding enhancement of* onc *expression by the viral promoter. The virus thus acts either through the effect of its enhancer alone or by distancing* c-onc *from the 'upstream' NRE.* **(f and g)** *Proviral insertion 3′ to* c-onc *in either transcriptional orientation. In these instances it appears that the virus can augment proto-oncogene expression only by virtue of its enhancer.*

mutant proto-oncogenes into the mouse germline has confirmed their oncogenic potential, whilst their inactivation by homologous recombination has provided valuable insights into their normal functions (Meuwissen et al. 2001). Insertional mutagenesis is also a prominent oncogenic mechanism for at least one representative of the hepadnaviruses; woodchuck hepatitis virus (WHV) often activates the c-*myc* or N-*myc* genes in the genesis of liver tumors that arise without the extensive cirrhosis that precedes HBV-associated cancers (Buendia 1994). By contrast, there is only fragmentary evidence for insertional mutagenesis in HBV-associated tumors. The reasons for the marked difference in mode of action between two similar viral agents are unknown.

So far we have focused on the capacity of integrated viruses to activate genes. The converse of this process, gene disruption by retroviral insertion, underlies some developmental mutations in laboratory mice (Lock et al. 1991). In such cases it is possible to reveal the disruptive effects of a single insertion by back-crossing to generate

a homozygous mutation. In somatic cells, gene ablation is an improbable outcome because it requires inactivating insertions at both alleles. Nevertheless, there are instances in which retroviral insertions have been shown to ablate gene function in tumor cells. Examples include the inactivation of p53 by insertion of Friend murine leukemia virus (MLV) in erythroleukemia (Ben-David et al. 1988) and the targeting of the neurofibromin gene (*NF1*) by BXH-2 virus in myeloid leukemia (Largaespada et al. 1995).

At first sight, mutagenic ablation might be thought to be more likely because it is less specific than activation, and so insertion anywhere within the coding region would destroy the integrity of the gene. However, mutational activation seems to operate by such a variety of mechanisms that it, too, can result from insertion at many locations near the activated gene (Figure 4). In the classic example of avian B-cell lymphomas, c-*myc* transcription is driven by the viral promoter in an LTR situated 5′ to the gene (Figure 4b). However, the subsequent discovery of enhancers in retroviral LTRs, their nonpolar action over long distances, and their effects predominantly on the nearest promoters now indicate that, in different circumstances, a viral LTR can augment activity of a gene either 5′ or 3′ to itself in either orientation (Figure 4e–g). Moreover, it is theoretically possible that an inserted provirus may activate a gene by simply separating it from *cis*-acting cellular repressors.

Although the focus of most current research is on the γ-retroviruses that infect the laboratory mouse, the mechanism of insertional mutagenesis is relevant in tumors induced by other members of the γ-retrovirus and β-retrovirus families. While FeLV appears to target a similar set of genes to MLV (Tsatsanis et al. 1994), a very different pattern emerges for mouse mammary tumor virus (MMTV), which frequently targets genes of the *Wnt* and *Fgf* families (Kapoun and Shackleford 1997). The relevance of insertional mutagenesis to human cancer has also come into focus recently with the observation of leukemia in gene therapy subjects which appear to have been induced by integration at the *LMO2* oncogene. This observation has led to a renewed interest in the specificity and consequences of retroviral integration in the host genome (Baum et al. 2003).

OTHER EVIDENCE IMPLICATING PROTO-ONCOGENES IN NEOPLASIA

A detailed consideration of the molecular and cell biology of neoplasia is outside the scope of this chapter, but the following brief survey is intended to provide some understanding of the basis of viral oncogenicity.

Two major lines of investigation have further incriminated proto-oncogenes in cancer.

1 DNA from certain tumor cells, but not DNA from their normal counterparts, can induce morphological transformation of, or confer tumorigenicity upon, appropriate recipient cells in culture. The genes responsible are often mutant members of the *ras* oncogene family, first encountered as the v-*onc* genes of certain murine sarcoma viruses. However, as with insertional mutagenesis by viruses, DNA 'transfection' has revealed further novel putative oncogenes whose properties, where known, are compatible with a role in neoplasia (Bishop 1987).
2 Many cancers display characteristic karyological abnormalities, typically deletions, translocations or amplification of identifiable regions of chromosomes. In some cases the genes affected by translocation and amplification are the cellular relatives of known v-*onc* genes; again a number of novel loci are deemed guilty by association (Rabbitts 1994).

In short, proto-oncogenes have been incriminated in neoplasia by a variety of phenomena, and some genes have been implicated in several ways. The mutations suffered by proto-oncogenes in tumor cells – be they single base changes, transduction or gross disruption by viruses or massive, microscopically visible aberrations in karyotype – have one (or both) of two effects: they change either the expression of the gene or the nature of its product.

'HIT AND RUN' MECHANISMS

The pattern of virus persistence in a tumor may be complex but is amenable to study. The same cannot be said for those instances in which a virus is implicated in tumor formation in vivo or cell transformation in vitro but in which it is impossible to demonstrate either persistence of a specific portion of the viral genome or integration in a limited region of host DNA. The virus in such cases is presumed to act transiently. It may operate by one of the mechanisms detailed above but the genes involved are required only in the early stages of tumor evolution and unknown selective pressures against the virus eliminate it during tumor progression.

The absence of bovine papillomavirus type 4 from the alimentary carcinomas that it causes may reflect such a mechanism, because at least some papillomaviruses are known to carry transforming genes. On the other hand, this virus, as proposed for herpes simplex viruses and cytomegalovirus in cervical cancer, may act as a mutagen, through an ephemeral association of its genome with cell DNA or, possibly, through the action of viral enzymes (Minson 1984; Macnab 1987). The mechanisms in either case are hard to study and investigators have invoked this 'hit and run' explanation only after eliminating other possibilities (McDougall 2001).

Indirect mechanisms

The second major category of pathogenic mechanism is also frustrating for the student of in vitro systems but is clinically significant, whether operating alone or in

concert with mechanisms outlined above. In these indirect, or extrinsic, mechanisms neither the cells of the tumor nor their ancestral lineage need ever have been infected by the causative virus; instead, tumors arise in response to virus infection of other cells, the nature of the response taking several forms.

Cell death or impaired function as a direct or indirect effect of virus infection can have different consequences depending on the type of cell affected. If the immune system is compromised the outgrowth of cells might be permitted from many tissues that had acquired neoplastic potential by various means; in practice, however, immunosuppression leads to increases in the incidences of a relatively small spectrum of tumors, a significant proportion of which are associated with viral risk factors (Figure 1). Cell death, or untoward cell proliferation, among hemopoietic tissues can also upset delicate homoeostatic cellular interrelations, and compensatory proliferation in other lineages may favor independent neoplastic alterations in these reactive cells.

A number of tumor viruses cause immune impairment (Table 6), probably by a variety of mechanisms. Immunosuppression by some viruses may be due to cytotoxicity, reflecting, in the case of avian reticuloendotheliosis viruses, the burden of intracellular unintegrated viral DNA. The immunosuppressive effect of HIV could also result simply from cytopathic effects on $CD4^+$ T cells, but the extent of infection does not seem sufficient to account for the degree of immune impairment. Various theories of HIV immunosuppression have been elaborated, including virus-induced autoimmune attack, T-cell apoptosis following nonspecific immunosuppression, cytokine dysregulation, and cell destruction due to chronic antiviral immune responses (Zinkernagel and Hengartner 1994). Two points should be noted at this juncture:

1. with the possible exception of HIV and its relatives, the tumor viruses that are immunosuppressive also seem to have efficient and direct means of inducing neoplasia
2. immunosuppression is the only indirect mode of viral carcinogenesis that does not necessarily involve cell proliferation as an early stage.

Death or damage to nonhemopoietic cells may likewise favor neoplastic change, but in uninfected cells of the same lineage that are dividing in an attempt at tissue regeneration. This is one way in which chronic hepatitis B or hepatitis C infections may increase the risk of primary liver cancer (Slagle et al. 1994).

Virus infection may also stimulate cells to produce growth factors of various types. In some cases, the viruses themselves carry growth factor-like genes, such as the EBV *BCRF1* gene which has homology with IL-10 (Morein and Merza 1991). When the producing cell itself possesses receptors for these factors, their effects can be autocrine with the virus acting directly, as described above. An example of such a process is the stimulation of IL-2 and its receptor by HTLV-I in infected T cells (Ruben et al. 1988).

A further example of viral interplay with host immunoregulatory systems is provided by the MMTVs, which encode superantigens. Endogenous MMTVs in the mouse genome express these polymorphic proteins that stimulate developing T cells via the Vβ of the αβTCR, leading to clonal deletion of reactive cells and a consequent bias in the Vβ repertoire of mature T cells. This phenomenon may be regarded as an aberrant outcome of viral sequestration in the mouse germline. However, it seems that the expression of these ligands on B cells is an important early event in establishment of infection by MMTV, because this may stimulate mature T cells to release growth factors that drive proliferation of the infected cell. Along the way, the virus usurps the host immune response to favor its own dissemination (Acha-Orbea and MacDonald 1995).

The potential stimulatory effects of viral antigens may also be due to their mimicry of ligands for receptors on a range of cell types. If these receptors modulate normal cell growth and behavior, chronic unscheduled binding of ligand analogues may lead to hyperplasia and then neoplasia. Such effects probably are widespread, and the oncogene of the spleen focus-forming component of Friend murine leukemia retrovirus is perhaps the best characterized example. This oncogene has no cell counterpart, being derived entirely from virus envelope gene sequences, but it appears to interact with the erythropoietin receptor, replacing the requirement for exogenous growth factors (Ruscetti 1999).

IMPLICATION OF VIRUSES IN THE ETIOLOGY OF CANCER

The pathogenic strategies just discussed are clearly crucial to the concepts of the genesis of virus-associated tumors but are only part of this complex process. Experimental, clinical, and epidemiologic observations all suggest that malignancy results from a step-by-step accumulation of stable cellular alterations whose occurrence reflects, and is greatly accelerated by, exposure to multiple risk factors. The age of the animal and the duration, intensity, and frequency of exposure to risk factors are important elements in tumor evolution, and these variables tend to obscure any causal relationship between virus infection and the eventual development of malignancy. We must take account of these other components if we are to understand the etiologic significance of viruses.

The influence of risk factors on viral carcinogenesis can be considered by dividing them into three major, but overlapping, categories:

1. factors associated with the virus infection and its effect on host cells

Table 6 *Viral functions implicated in cancer*

2 factors that determine the evolution and properties of neoplastic cells
3 factors that affect the host response to both virus and tumor.

We can consider in turn the interplay of these factors during three arbitrary stages of tumor development:

1 the successful infection of the organism by a virus and, when the virus acts by a direct means, its infection of the tumor cell lineage
2 the conversion within the tumor cell lineage of a normal cell to neoplastic growth and behavior
3 the survival and growth of its descendants to form a detectable tumor.

An assessment of the relative importance of the different risk factors at each stage of tumor development is shown in the histogram in Figure 5. In this diagram the three stages of development are shown on the abscissa, which is thus a time scale axis; it is, however, impossible to draw this to scale. Stage 2 is probably the longest period; important stage 2 events probably often precede those in stage 1.

Virus infection/transmission

An animal becomes infected with an oncogenic virus by one of three routes (Weiss 1984). The first is genetic transmission, by which most individuals, of many species, have acquired endogenous retroviruses during evolution. These viruses seem to be nonessential but innocuous passengers in the genomes of their hosts and they are often xenotropic (i.e. capable of replication

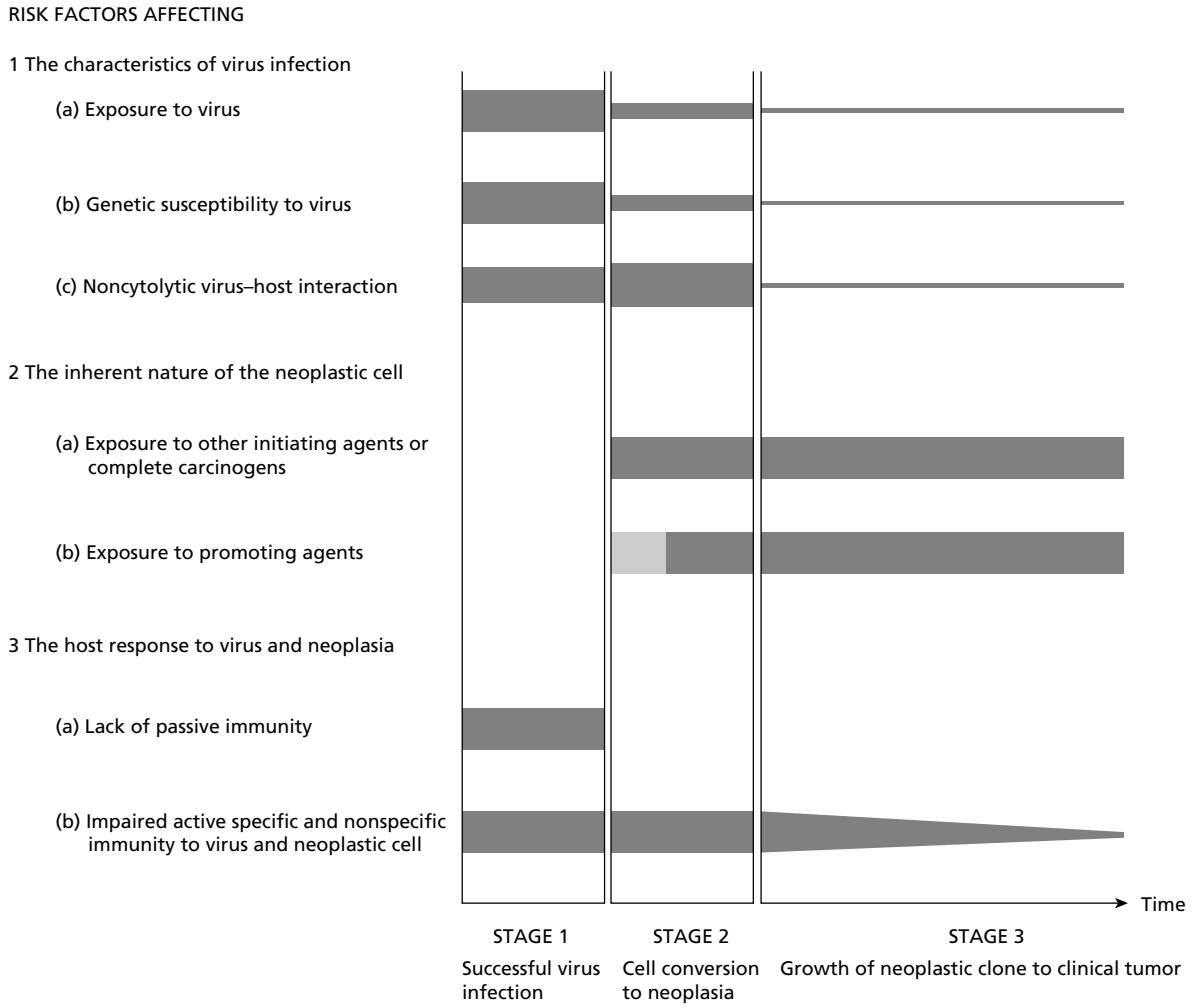

Figure 5 *Risk factors in viral carcinogenesis: the relationship between the arbitrary stages of virus-associated neoplasia, the features of the neoplastic process, and the risk factors that influence each feature. The stages of neoplasia are shown on the abscissa. The breaks in the time axis indicate that these stages vary in length and they are not shown to scale (in general, stage 1 is likely to be relatively short and stage 2 is usually the longest period). The risk factors affecting any of the three features characterizing virus-associated neoplasia are shown on the ordinate and they may operate at different, and often more than one, stages of the disease process. The thickness of the bars indicates the relative importance of each risk factor at each stage of neoplasia, broken lines indicating periods at which the risk factors are of no or uncertain significance. (Modified, with permission, from Wyke and Weiss 1984.)*

only in other species). A clear exception to this harmlessness is that certain strains of mice harbor endogenous viruses that are ecotropic (i.e. they can infect mouse cells). Moreover, these viruses evolve by recombination with other defective endogenous proviruses, generating variants with enhanced leukemogenicity (Stoye et al. 1991). Comparable variants of altered, if not augmented, pathogenicity can also arise by recombination of FeLV with endogenous cat retroviruses (Neil et al. 1991). In both mice and cats the recombinant viruses reveal altered viral envelope glycoproteins, some of which have an increased propensity to bind to and stimulate proliferation of immune-responsive and other cells.

The second route, congenital transmission of exogenous viruses across the placenta or oviduct, is important in the case of leukemogenic avian, feline, and bovine retroviruses. However, for these and many others the third route, horizontal transmission peri- and postnatally is also significant. Whereas the papovaviruses are hardy, the enveloped herpesviruses and retroviruses are far more labile; their horizontal spread is therefore more efficient when animals are grouped together and make close contact with carriers. Moreover, such conditions increase the risk of repeated exposure to high doses of virus early in life, a pattern which, in turn, appears to encourage the eventual appearance of neoplasia.

With regard to the routes of transmission, the pattern of virus spread is also greatly influenced by its site of replication in the animal. Thus, for FeLV and EBV, free virus is shed in the buccal cavity and transmitted in saliva. Marek's disease virus of fowls, on the other hand, replicates in feather follicle epithelium and is spread in dander, whereas BLV and HTLV remain cell-associated and require the transmission of whole cells. In the case of the last two viruses, iatrogenic transfer and 'flying pin' arthropod vectors might be expected to be significant routes of infection, and epidemiologic data support this notion.

Genetic susceptibility to viruses

All viruses require the means to enter a cell, express their genomes, and assemble progeny for spread to other cells. Interspecies variation in the susceptibility of cells to viruses – often associated with severe constraints on the virus life cycle – are taken for granted but there can also be pronounced variation within a species. In cases of virus-associated neoplasia, such variation is indicated by clustering of tumor incidence. Clusters are often due to variation in the other risk factors discussed here, but difference in virus susceptibility is a likely cause when clustering is demonstrably familial. In domestic animals, where breeding is often controlled and one male can sire many dispersed offspring, it is easier to discern familial clusters. The clusters of, for example, bovine leukosis, reflect genetic factors that are not well defined, but in other instances the basis for the underlying enhanced susceptibility is better understood. The species in which this has been studied most comprehensively is, of course, the laboratory mouse (Rosenberg and Jolicoeur 1997).

The need for entry of virus into cells provides a crucial barrier to infection; in many cases, efficient penetration is highly specific, not only for the whole animal but also for particular types of cell within the host. Retroviruses enter cells whose surfaces bear receptors to which the viral envelope glycoprotein can bind. In chickens, receptors are found on a wide range of cell types but their specificity (and hence host susceptibility to virus) reveals genetically determined polymorphisms between individual birds (Payne 1992). Other receptors are of limited distribution within the host: human CD4 lymphocyte antigen is an important component of the HIV-1 receptor, this stringency explaining in part the tropism of HIV-1 for a particular T-cell subset (Dalgleish et al. 1984). These receptors do not of course exist merely to facilitate virus penetration and, indeed, not all binding sites serve this role. They clearly have structural or other functional purposes on the cell surface. For the mammalian type C retroviruses, related families of transmembrane transporter proteins for basic amino acids and phosphate have been identified as mediators of viral entry (Cunningham and Kim 1994). However, the relevance of these to oncogenesis seems to be slight, as there is little evidence of effects on cell growth and viability emanating from virus binding to these receptors.

EBV gains entry to B cells via binding to the complement receptor molecule CR2 (Nemerow et al. 1987). Other oncogenic DNA virus receptors have yet to be definitively identified. Once inside cells, viruses may do some damage, which will, however, be greatly limited by any further restrictions on their replication and spread. For instance, retroviruses are subject to both physiological and genetic constraints after penetration. For the type C retroviruses, stable integration of a complete DNA transcript of the virion RNA genome can occur only in cells that synthesize DNA; on the other hand, the early gene functions of polyomaviruses can themselves stimulate DNA synthesis. The host range restrictions of ectropic MLV mediated by the mouse Fv-1 locus also operate during this early part of the infectious cycle. Recently, the retroviral LTR (see Figure 4) has attracted considerable attention and there is a wealth of evidence to suggest that its potency varies with cell type. Cellular factors interact *in trans* with the LTR enhancer to modulate the level of transcripts mediated by this element in a given cell and hence the extent of viral replication, the oncogenic potential of the virus, and its cell tropism (Tsichlis and Lazo 1991). Thus, the pathogenesis of, for example, retrovirus-induced mouse leukemia is a very complex process in which both the virus and the tumor cell evolve. When virus infection of an appropriate host results in proviral insertion at a specific site, the expression is stimulated by one or more

of a range of cell genes. The amplitude of this expression may depend on the potency of the viral LTR in that cell (Morrison et al. 1995).

Noncytolytic virus–host interactions

Some tumor-associated viruses, such as HBV and many retroviruses, can be released by cells without compromising viability, but for many others cytolysis is necessary for escape of virus. Cytolysis is, of course, incompatible with direct mechanisms of virus oncogenesis, so neoplasia is likely to be a rare and aberrant consequence of infection by these viruses. In such cases, either the host restricts the later stages of virus replication or the virus is defective in directing these events, but, in both instances, viral functions needed to induce neoplasia are retained.

Two other properties of tumor viruses are worth mentioning here: virus integration and latent virus infection. The viruses of all families that include directly oncogenic members can exist as DNA within the cell, inserted in the host chromosome. This may be a rare outcome of infection or, as with retroviruses, an essential part of the virus life cycle. Virus integration is obligatory for oncogenesis by insertional mutagenesis, but there seems to be no reason why it should be required for other forms of oncogenesis. Indeed, as virus genomes are absent from some tumors for which viruses are considered risk factors, integration is presumably not essential – at least in the later stages of tumor evolution. Poxviruses, although not true tumor viruses, need special consideration because they can induce proliferating lesions, probably through the action of viral genes that encode molecules resembling cell growth factors (Opgenorth et al. 1992) but the lesions produced do not progress to full-blown cancer. Nevertheless, infection can be fatal due to concomitant inflammatory disease. It is possible that poxviruses fail to induce tumors because they replicate in the cytoplasm, never integrate, and so do not achieve a sufficiently stable association with the host cell. A number of RNA viruses also achieve persistent infections, yet they rarely, if ever, integrate and only one representative (hepatitis C virus (HCV)) has so far been incriminated in neoplasia. Integration is clearly important in achieving a stable infection but may have additional undefined significance.

Latency is a characteristic of two families of oncogenic viruses: the retroviruses and the herpesviruses. Prolonged latent infection is a common sequel of primary FeLV infection in cats. It is associated with a humoral and cellular immune response and can be abolished by treatment with immunosuppressive agents (Rojko et al. 1982). Without such insults, however, this form of latent infection tends to resolve in recovery with subsequent immunity (Pacitti and Jarrett 1985). Latent infection with BLV has also been described but in this case a non-immunoglobulin plasma protein seems to be involved in virus suppression (Gupta and Ferrer 1982). Like those of many endogenous retroviruses, latent exogenous genomes may be in the configuration of inactive chromatin, which is highly methylated. This has practical significance because tumor cells do not usually express their resident viral genomes unless the animals are immunosuppressed or the cells are cultured, with or without agents intended to activate silent genomes. At the mechanistic level, the role of latency in neoplasia is not obvious, but, like integration, it may serve primarily to ensure persistence of the viral genome, thus facilitating its interactions with the other risk factors germane to neoplasia.

EBV latency is a paradigm for this mode of infection by the γ-herpesviruses and appears to be critical to virus persistence and central to its involvement in tumors (Rickinson and Kieff 1996). Human peripheral blood cells can be transformed and immortalized by EBV infection in vitro. These latently infected cells express a subset of the EBV genome comprising six nuclear proteins (EBNA1, EBNA2, EBNA-LP, EBNA3A, EBNA3B, and EBNA3C), as well as two oncogenic membrane proteins (LMP1, 2) and small EBV RNAs (EBER). EBV-positive tumor cells display a restricted subset of these genes. The minimal expression pattern is exemplified by Burkitt's lymphoma, where viral expression is restricted to a EBNA-1 and EBERs. A more complex pattern is observed in nasopharyngeal carcinoma, which includes the oncogenic latent membrane proteins (LMP-1,2) as well as EBERs and EBNA-1. A variation on this theme is seen in EBV-associated lymphoproliferative diseases of transplant recipients and AIDS patients, which express EBNA-2 in addition to the list for nasopharyngeal carcinoma. These distinctive patterns reflect the critical role of the immune system in containing EBV infection and the consequences of its compromise in neoplastic disease and immunosuppressed states. They probably also reflect differences in the relationship of EBV to tumor initiation and maintenance in these diverse neoplastic diseases.

A similar pattern is emerging for Kaposi's sarcoma-associated herpesvirus (KSHV), where HIV appears to be the primary cofactor, revealing its latent oncogenic properties and enabling a wider range of viral products to be expressed in the tumor cell (Schulz and Neil 2002).

Viruses and the multistep development of neoplasia

Many of the viruses that transform cells in vitro carry oncogenes of which the activity is under the control of powerful viral regulatory elements (see Figure 4). Oncogenes – perhaps aided by a spreading virus infection – are very potent carcinogens that rapidly induce tumors in host animals. In some circumstances, however, oncogene-mediated viral carcinogenesis is far

less efficient and the appearance of a neoplastic cell phenotype requires other genetic or epigenetic events such as the loss of tumor suppressor genes or the acquisition of additional, activated oncogenes. There is abundant evidence for this. Some tumor viruses carry more than one oncogene, each of which contributes to their tumor-inducing capacity. In the example of the retrovirus avian erythroblastosis virus, *erb*-B encodes a transmembrane protein [epidermal growth factor (EGF) receptor] and *erb*-A a nuclear protein (thyroid hormone receptor) (see Table 4). Other examples are the presence of the c-*myc* nuclear oncogene and the protein kinase oncogene *mil*/*raf* in avian carcinoma virus Mill Hill virus 2 (ACMHV-2), and the presence of two nuclear oncogenes, *myb* and *ets* in avian myeloblastosis virus (AMV).

Further evidence of the cooperative action of multiple genes in lymphoma development comes from the γ-retroviruses, in which multiple different insertional mutagenic events can be observed in a single tumor (Tsichlis et al. 1985; Tsatsanis et al. 1994). Furthermore, mice carrying an activated oncogene in the germline may show greatly accelerated tumor onset when infected with the virus, and activation of cooperating genes by insertional mutagenesis occurs at high frequency. Further evidence of the cooperative action of these genes is provided by the strongly synergistic effect on tumor development of crossing mice carrying different activated oncogenes (e.g. c-*myc* and *pim*-1) (Jonkers and Berns 1996). Similarly, MMTV appears to be capable of mediating multiple mutational hits by insertion at synergistic oncogenes of the *Wnt* and *Fgf* families (MacArthur et al. 1995). The relatively unrestricted replication of these agents in the persistently infected host may account for their unusual propensity for insertional mutagenesis.

In naturally occurring cancer, the requirement for multiple cellular changes is mirrored in the time- and risk-factor-dependent pattern of tumor development. Many clinically important tumor viruses, particularly those of humans, need the operation of additional chemical, physical, or infectious risk factors to initiate or promote neoplasia (see Tables 1, 2 and 3). Because these viruses are incomplete carcinogens, it is not certain whether they act as initiators or promoters of oncogenesis.

Viruses have often been considered initiators, for a number of reasons. Initiation in experimental systems is a dose-dependent, irreversible event with many hallmarks of mutation (Montesano and Slaga 1983), and direct models of virus oncogenesis either induce or introduce mutant genes. Moreover, virus infection is often observed early in life in the susceptible individual, perhaps before exposure to other likely risk factors. However, aside from instances of possible transient effects, virus-induced cancer is often associated with persistent infections, virus integration, and possibly latency. Infection early in life may simply be a prerequisite for achieving persistence, a prolonged exposure to virus that can be significant in two ways. First, it may increase the chance of crucial, if rare, virus–cell interactions. Second, and this seems particularly relevant to viruses that act indirectly, it may enhance the possibility that other environmental risk factors that may be encountered can be influenced by a chronic viral tumor-promoting activity. Some instances, however, are not clearcut. Consider, for example, tumor induction by EBV and HTLV-I: both seem to stimulate a proliferation of lymphoid cells that is strictly neoplastic (in that it is driven from within the cell and results from a 'mutation') but which resembles hyperplasia in being polyclonal. These viruses seem to behave as tumor promoters, and subsequent clonal events such as c-*myc* translocation in EBV-associated Burkitt's lymphoma are more likely to be the result of initiation. It seems that the concepts of initiation and promotion that have been so fruitful in studying experimental carcinogenesis are not so readily applicable to viral cancer. The consequences of virus infection are, however, clearly capable of contributing to several stages of neoplasia.

The host response

The ability of the infected animal to limit both virus infection and the multiplication of neoplastic cells is of great importance in virus-associated neoplasia, particularly the leukemias in which the tumors themselves are prone to perturb both specific and nonspecific immune regulation. Establishment of virus persistence increases the chance of viral pathogenic mechanisms coming into play; persistence can often be achieved by exposing a young animal, with waning maternal immunity, to large and possibly repeated doses of virus, resulting in impaired ability to limit the extent of the infection. Episodes of immune impairment later in life, due to nutritional or hormonal factors, disease or other physiological stresses, can reinforce this effect or even favor infection of a previously virus-free animal. When the viral risk factor is itself an immunosuppressant (see Figure 5) the problem is exacerbated, and, once a tumor burden develops, it may reinforce the predisposing impairment.

An intimate association with compromised immunity is often seen in the natural history of virus carcinogenesis. Examples from avian, feline, and human hemopoietic neoplasms, in which the virus infection contributes wholly or partially to the immunosuppression, have been given above. In other instances, another risk factor is responsible. Thus, an immunosuppressant in bracken fern seems to be important in the etiology of papillomavirus-associated alimentary carcinomas in cattle (Jarrett 1985; Beniston et al. 2001). In humans, iatrogenic immunosuppression is associated with an increased incidence of certain tumors, many of

which had prior association with a virus risk factor. Indeed, so striking is this that Kinlen has suggested that all human tumors of which the incidence increases in immunosuppressed patients may have a viral component in their cause (Kinlen 1992). In short, the host response seems to be more important in controlling virus infection than other aspects of cell neoplasia.

The search for new viruses

There are three important motifs in naturally occurring viral cancers in animals and humans:

1 virus
2 immune impairment
3 co-carcinogen.

The first two components appear to be particularly important in most animal tumors, whereas the third is of greater importance in humans. These must all be considered in assessing the roles of other potential tumor viruses.

The most profitable tumors for study are those showing clustering that can be familial, geographical, or social/occupational, implying important genetic or environmental risk factors, both of which can point to viruses. Another important clue is any evidence of increased tumor prevalence in immunosuppressed individuals.

Both intact animals and tumors must be examined for characteristics of virus infection. Virus isolation from tumor material may require culture of tumor cells to demonstrate any latent virus, perhaps with addition of hormones, or of chemicals such as bromo- or iododeoxyuridine to activate endogenous viruses, or 5′-azacytidine which inhibits cytosine methylation. Virus can sometimes also be detected by electron microscopy or immunological techniques. It is important to try to discover an appropriate cell type for virus propagation in vitro because the tumor itself is often an unsuitable host. The complexity of the mammalian genome was a barrier to solving this problem by subtractive hybridization methods, but polymerase chain reaction (PCR)-based techniques can now identify small amounts of foreign DNA in tumor cells (representational difference analysis). This strategy led to the discovery of a new human herpesvirus (KSHV) in Kaposi's sarcoma cases (Chang et al. 1994).

Isolation of a candidate virus provides the opportunity for a more detailed study of its association with the tumor. If, however, isolation fails, much can be learned by comparison with known tumor viruses together with the screening of tumor cells for molecular evidence of viral infection and examination of intact animals for epidemiological clues. If infection with a virus is common in a population, features of the infection peculiar to the tumor-bearing hosts should be sought. Is the infection unusually persistent? Is the serological response abnormal? Is the virus in the tumor defective? Are unusual viral antigens expressed? Even when a virus cannot be identified, a specific tumor antigen may be an important clue to a viral etiology.

Epidemiological evidence is crucial in humans, in whom it is impossible to test a causal role for the agent by virus inoculation. Case–control studies can associate the virus with the tumor, and laboratory investigations will establish the features of high- and low-risk groups. Retrospective and, ideally, prospective studies of high-risk groups can establish a temporal relationship between virus infection, other risk factors, and tumor development. This knowledge can then serve as a basis for the management of the tumor.

PRINCIPLES OF THE MANAGEMENT OF VIRUS-ASSOCIATED CANCER

Although little is known of many aspects of the pathogenesis of virus-associated tumors, the knowledge that a virus is implicated can be used to try to manage the disease at any of three arbitrary stages of virus neoplasia described earlier (Figure 5). Two points should be remembered. First, a wider range of prophylactic measures can be applied in veterinary medicine (where the health of the herd can override the survival of the individual) than in human practice. Second, for all tumors in which a virus is implicated, the detection of virus infection at any stage of the disease might be of diagnostic or prognostic use. This is clearly the case in the few diseases in which infection often leads to tumor formation. However, even when neoplasia is rare, detailed knowledge of the role played by the virus might identify features of the infection that are characteristic of hosts at high risk.

Prevention of virus infection

Before infection, steps can be taken to:

- decrease the concentration of virus in the hosts' environment
- increase the natural (genetic) resistance of host populations
- increase the resistance of the hosts by active or passive immunization.

THE SOURCE OF VIRUS

This is determined by the density of symptomatic or asymptomatic carriers in the population, the ability of the virus to survive outside its host, and whether other animals act as natural reservoirs for the virus. Many tumor viruses are species-specific and in practice only the first two factors are amenable to prophylactic measures.

The identification of carriers often requires specialized techniques to detect virus infection. It is thus costly and further action is effective only when the carrier can be killed, cured, or isolated from the susceptible population.

For these reasons, identification of human carriers poses ethical problems but can be important for several groups of patients. The first are those whose habits place them at particular risk, for example intravenous drug abusers in the case of HIV and HBV infections and the sexually promiscuous in the case of papillomavirus and herpesvirus infections. The second are those who have acquired iatrogenic infections, such as HIV and HBV from contaminated blood products. The third are mothers infected with HTLV, where breast milk can be a very important but avoidable means of transmission.

Identification of carriers can be useful in the control of avian, feline, and bovine lymphoid leukemias. A small proportion of cats infected with FeLV do not develop immunity and remain viremic. Such animals can either be removed from colonies or identified before introduction into virus-free groups. Eradication of enzootic bovine leukosis is greatly assisted by tests for virus carriers, whose lineage can be maintained free of virus by the transfer of well-washed embryos (with the zona pellucida intact) to virus-negative recipients.

Improved hygiene to reduce the source of the virus is probably of little significance within susceptible host populations but, in combination with appropriate husbandry, can reduce the dissemination of disease between local concentrations of animals such as the spread of ALV from one poultry farm to another. Many tumor viruses are highly susceptible to chemical disinfectants, drying, and other inactivating agents, but horizontal and congenital spread depend on such intimate contact between hosts that disinfection is impracticable. Papillomas and enzootic bovine leukosis are exceptions to this because the causal viruses can be spread on the instruments of stockmen and veterinarians. Another possible measure, applicable to BLV and HTLV-I, is the control of insects that may spread infection. The social and hygiene practices in many Western countries delay some EBV infections until puberty or later, but these increase the incidence of infectious mononucleosis. A delay in the age of acquisition of EBV infection in Africa and Asia might reduce the incidence of Burkitt's lymphoma or nasopharyngeal carcinoma, but this has not yet been demonstrated. However, one virus-associated human neoplasm for which a change in habits should reduce incidence is carcinoma of the uterine cervix. As with other venereally transmitted infections, the spread of papillomavirus and herpes simplex virus (HSV) type 2 has been favored by promiscuity and changes in contraceptive practices.

THE GENETIC SUSCEPTIBILITY OF HOST ANIMALS

The selective breeding of genetically resistant stock is possible only in animals, and particularly in those that have a short generation time. It has been successful in reducing the incidence of avian lymphoid leukosis; the causal virus exists in the field as two major subtypes, characterized by the presence of particular glycoproteins on the viral envelope. These glycoproteins interact with specific cell surface receptors to allow the viruses to penetrate the host cells. Strains of domestic chicken have been bred that lack the surface receptors for the field strains of ALF and these birds are resistant to infection (Crittenden and Motta 1969). Some strains partly resistant to lymphoid leukosis apparently permit infection but not tumor development. A similar genetic resistance is seen in the production of Marek's disease lymphomas.

IMMUNITY TO VIRUS INFECTION

Although a number of commercial vaccines exist for oncogenic viruses of animals, proposals to produce vaccines against human oncogenic viruses are controversial, for several reasons.

- In many instances the role of the virus in the tumor is uncertain; indeed, proof of a causal role may rely on the prophylactic effect of vaccination. This leads to the dilemma of whether to embark on such measures before they can be shown to be necessary.
- Tumor production may be a rare outcome of infection by a widespread and not very pathogenic virus.
- The presence of many latently infected carriers and the frequent acquisition of infection early in life (e.g. with human herpesviruses) will limit vaccine efficacy.
- Because tumors can result from an aberrant virus–cell interaction, a traditional type of vaccine, based on inactivated or attenuated virus, may itself pose a risk of oncogenicity. This last objection might be overcome by the use of purified immunogens either produced by genetically manipulated portions of viral genomes or synthesized in the laboratory.

However, the first two considerations suggest that the returns (in terms of improved health of the human population) may justify the outlay only if three conditions are fulfilled:

1. the virus causes significant disease in addition to its oncogenic potential (as is the case with HIV and HBV)
2. the populations concerned are clearly defined, small and at high risk
3. the virus is the only clearly defined risk factor in the genesis of a common tumor (as with EBV-associated nasopharyngeal carcinoma).

The first successful commercial vaccines against a neoplasm were produced for Marek's disease and have proved of great value to the poultry industry. Avirulent strains of the virus, either natural or artificially attenuated, have been used as vaccine, as has a related herpesvirus of turkeys; continual modification of the vaccine, however, has been necessary to try to keep up with the emergence of highly virulent strains (Schat

1987). The vaccine virus strains establish a latent infection and induce tumor-associated surface antigens in lymphoid cells, sometimes with minor cytopathic effects and neuritis. There is, however, no immunosuppression and vaccinated birds resist challenge with oncogenic virus (Calnek et al. 1979), apparently by an immunity directed against both viral and tumor antigens.

Approaches to vaccination against human herpesviruses have been more conservative, most efforts being directed to the testing of recombinant subunit vaccines in animal models. Using recombinant subunit vaccines based on viral surface glycoproteins, protection against infectious virus challenge has been achieved against EBV in a cottontop tamarin model, and against HSV in mice (reviewed in Morein and Merza 1991). While it would be desirable to eradicate both these viruses from the human population, the case for large-scale vaccination is not clearcut.

Recombinant subunit vaccines based on HBV surface antigen have been available since 1982 and have proved effective in reducing the incidence of infection in selected at-risk groups. However, these measures have had little impact on the overall incidence of infection in the population, leading to calls for mass vaccination programs to be extended (Rizzetto and Zanetti 2002).

Vaccines made from ground-up wart tissue have long been used for prophylaxis and therapy of papillomas in animals. This empirical approach illustrates the potential for vaccination against papillomavirus infection, but is clearly incompatible with modern quality-control standards for human medicine. More recently, recombinant gene products of bovine papillomavirus, both early and late genes, have been efficacious in preventing warts and in accelerating rejection (Campo 1995). Translation of these results to human vaccination is complicated by the multiplicity of HPV types and our limited knowledge of the natural history of HPV infections (Galloway 1994).

A number of commercial vaccines have been developed for feline leukemia, including inactivated virus, infected cell extracts, and recombinant subunit *env* vaccines (Jarrett 1994), and attempts to produce a BLV vaccine are also under way.

Although prophylactic vaccination is also considered highly desirable as a means of containing the HIV epidemic, trials of candidate subunit vaccines to date have failed to demonstrate efficacy. Experiments with animal lentivirus models such as simian and feline immunodeficiency viruses have shown only weak protection or short-term suppression of virus replication with conventional subunit or inactivated virus vaccines, and the problem of vaccine escape due to strain variation is significant (Mwau and McMichael 2003).

ANTIVIRAL THERAPY

Another approach to the control of oncogenic viruses (one popular with the pharmaceutical industry) is to try to limit the infection – usually after it is clinically evident – with antiviral chemotherapy. This, too, poses problems inherent in the close symbiosis between viruses and their host cells, because drugs must be devised that are selectively toxic for the virus. One approach is to direct research to the development of inhibitors of processes essential to the virus but dispensable by the cell, such as reverse transcriptase. Within these constraints, some widely used and moderately effective drugs have been developed against, for instance, herpesviruses and retroviruses. These drugs may assist in the control of virus replication but in their current modes of use have shown no beneficial effect on tumor development or on established cancers. For example, the most widely used antiretroviral agent, azidothymidine, was first tested as a potential anticancer agent but its long-term use in AIDS patients does not appear to reduce, and might conceivably increase, the incidence of non-Hodgkin's lymphoma (Pluda et al. 1990).

The use of interferons to control virus-associated cancers was considered an exciting prospect in the last decade but clinical trials have, in general, been disappointing. Striking exceptions have been the effects of interferon-α in virus-associated laryngeal and genital papillomas and in hairy cell leukemias. However, effects other than antiviral activity may be involved in the former examples (Gangemi et al. 1994) while in the latter case the ability of interferon to induce cell differentiation seems to be the most likely mechanism (Vedantham et al. 1992).

Prevention of cell conversion to neoplasia

The problems of tackling viral infection suggest that other potentially avoidable risk factors (see Tables 1, 2, and 3), which tend to operate in association, might provide easier targets for preventive measures. Such hopes, however, seem largely misplaced. In humans these risk factors include habits (notably smoking), dietary factors (which may be even harder to eliminate than smoking unless, like aflatoxin contamination, their deleterious effects are obvious), and other diseases. The most striking example of the last is malaria, a risk factor in Burkitt's lymphoma in certain tropical areas but also a major disease problem in its own right in many parts of the world. Indeed, the reduction or elimination of some of these risk factors would have benefits far beyond the postulated decrease in cancer incidence. This is so self-evident that there must be doubt as to whether the incentive of cancer prevention per se will succeed where other imperatives have failed.

Therapy of virus-associated cancers

Once a virus-infected cell has become neoplastic, the prevention of further tumor growth depends on therapy

rather than prophylaxis. But with virus-associated tumors, the detection of infection at any stage of the disease might itself influence prognosis. In cases in which neoplasia is a rare outcome of virus infection, knowledge of the role played by the virus might identify features characteristic of hosts at high risk. Such knowledge has been used, for instance, in attempts at early diagnosis of nasopharyngeal carcinoma by screening populations at risk in China for EBV-specific salivary IgA (Zeng et al. 1982).

When viral etiology is established, immunotherapy might be considered as a means of achieving regression. Indeed, early experimentation demonstrated that most virally induced tumors were quite readily rejected, unlike those without obvious viral etiology (Klein and Klein 1977). However, these experiments involved the inoculation of immunocompetent animals with tumors expressing readily detectable viral antigens. By contrast, the human malignancies most tightly linked to virus infection are seen in the context of obviously impaired immunity (e.g. AIDS or transplant patients) or express very little if any viral antigens [e.g. HTLV-I-associated adult T-cell leukemia (ATL), Burkitt's lymphoma]. Moreover, the latter tumors may have arisen in individuals with specific deficits in their immunological repertoire, as suggested by associations with specific types of major histocompatibility complex. In these contexts, immunotherapy seems much less promising and it may be necessary instead to consider the means of repairing the defective response. One way to achieve this may be to create tumor cell vaccines by transfection with co-receptor or cytokine genes. Ironically, the retroviruses have recently found a role as vectors to mediate this type of gene therapy for cancer (Vieweg and Gilboa 1995).

Papillomavirus-associated neoplasms have long been treated with extracts of tumors. For example, treatment of bovine ocular squamous cell carcinoma (a common neoplasm in light-skinned cattle in areas of high sunlight) with an allogeneic tumor extract resulted in remissions (Hoffmann et al. 1981). However, it is not clear whether viral antigens were targets in the regression of this malignancy. As discussed earlier, the possibility that vaccines against HPV-16 and 18 might be able to cause regression of cervical carcinoma is now under experimental trial (Frazer 2002).

Finally, if viral genes can be shown to play a role in the maintenance of the tumor state, then direct inhibition of their expression or even their downstream effectors may be a route to therapy. For example, antisense inhibition of NF-κB was found to limit the growth of HTLV Tax-transformed cells in a mouse tumor model, while antisense to Tax itself was ineffective (Kitajima et al. 1992).

CONCLUSIONS

In recent years, research on tumor viruses has identified some of the genetic lesions that underlie neoplasia and has led to some remarkable advances in basic cancer research. These studies are now influencing areas of cell biology and biochemistry that seem far removed from their virological origins. At the same time, however, tumor viruses have become more important to the virologist. We now appreciate that viruses are often one of a complex of risk factors that predisposes to a significant proportion of human disease. Although the part they play often results from an insidious and intractable pathogenic process, they are, in theory, avoidable risk factors. As such, they may provide the key to the management of many cancers.

INTRODUCTION

Epidemiology describes the occurrence of illness in populations and, by means of specific study designs, facilitates analysis of the risk factors that determine its distribution. Such investigations are often observational and do not involve experimentation or intervention but, rather, they gather and interpret events as they occur in nature. In the process, the occurrence of diseases is quantified according to their characteristics. Hypotheses concerning etiology and other variables are generated and are tested using statistical techniques. Epidemiology also provides experimental approaches for evaluating the efficacy of interventions such as vaccines to prevent or drugs to treat disease. Infectious diseases were the primary concern of epidemiologists for many years, and concepts were developed to evaluate the infectious process in populations. Now, most epidemiologists work on noncommunicable diseases, and methods originally developed to study acute infections are being used to evaluate etiology and risk factors for conditions such as coronary heart disease and cancer.

Whilst similar methods are now employed to study both communicable and noncommunicable diseases, the unique nature of replicating agents makes certain techniques more relevant to infectious illnesses, especially in examining questions of etiology. Debate has raged about the appropriateness of separating causes of diseases into 'necessary' and 'contributing' (Susser 1973). For example, it is impossible to produce a case of polio without the poliovirus, although contributing factors may be involved in determining the consequences of the infection, i.e. whether disease develops and how severe it is. Epidemiological approaches may also be required to evaluate some of the basic characteristics of infectious agents in humans, such as the infectious dose, which is important in terms of both the amount of pathogen required to initiate infection and the ease and likelihood of transmission. When animal models are available, many of these variables can be estimated. Results may or may not be applicable to humans, so epidemiological studies are needed for confirmation. They are essential when no animal model is available.

When dealing with viral infections (as opposed to those caused by other infectious agents), epidemiological principles are modified only because of characteristics of the pathogens. Most reflect differences in the ability of the agents to persist in the environment (typically more limited with viruses) and the comparative lack of the intermediate hosts that exist with animal parasites. Features such as the possibility of persistent infection and induction of chronic disease and malignancies are not unique to viruses, but are certainly more characteristic of infection with some of them than with other

types of agents. In this chapter, the examination of the epidemiology of viral infections emphasizes the elements that are unique to viruses, but the discussion is not limited to them. More general issues are also covered and viral infections serve as illustrations of the principles and methods discussed.

CLASSIFYING MECHANISMS OF VIRAL TRANSMISSION

Direct transmission

In the cycle of infection, the period during transmission of the agent from one host to the next is when the virus is exposed to the environment and therefore most vulnerable. Systems have been developed to divide the transmission mechanisms of infectious agents into different categories and subcategories. There are classification systems based on portals of entry and exit of the agent to and from the host (Fox et al. 1970). That shown in Table 1 is based on duration and route in transit from one host to the next, but some categories are limited to specific portals such as the skin or the respiratory tract (American Public Health Association 1985). The major division is between direct transmission, which is essentially immediate, and indirect transmission, which is delayed. Direct contact generally implies no exposure of the agent to the environment. This type of transmission occurs during sexual intercourse, as with human immunodeficiency virus (HIV) or hepatitis B, or during direct skin contact, as with herpes gladiatorum, a herpes simplex infection of wrestlers transmitted as they rub their skin against that of an opponent (Belongia et al. 1991). In most cases, virus-containing fluids are involved and the viruses are often cell associated. Direct contact includes, by extension, vertical transmission which may take place transplacentally, during the birth process or in breast milk. All these extended mechanisms are documented for HIV, which can be transmitted directly but is not well transmitted when the agent comes in contact with the environment (Friedland and Klein 1987).

Table 1 *Principal mechanisms of transmission*

Principal mechanisms
Direct (essentially immediate)
Contact (touching, kissing, sexual intercourse, etc.)
Large droplet – limited distance
Indirect
Vehicle-borne
Indirect contact – fomites
Other inanimate objects and biological substances (water, milk, urine, stool, etc.)
Vectorborne
Mechanical – without multiplication
Biological – with multiplication
Dusts and airborne droplet nuclei (aerosols)

Droplets of various sizes are expelled as part of respiratory discharges; the larger droplets, greater than 5 μm in diameter, settle out rapidly and do not spread further than about 1 m, rendering this form of transmission essentially immediate. Thus, even though the previously and the newly infected hosts are not in contact with each other, this is also considered to be a form of direct transmission, because of the limited transit time of this class of infected droplets which do not stay in the air for long periods. Agents potentially destroyed by longer exposure to the environment can still be transmitted by this mechanism. Rhinoviruses are spread by large droplets. As a result, rhinovirus disease transmission, which generally peaks in the autumn when schools reopen, is in fact a summation of mini-outbreaks produced by concurrent dissemination of many different serotypes (Monto et al. 1987). Some large droplets evaporate to become aerosols that may stay suspended and remain infectious for long periods. Influenza is spread by both large droplet and aerosol; a single viral subtype is generally responsible for outbreaks (Couch et al. 1966), in contrast to the relatively limited nature of transmission via large droplets alone. The childhood exanthemata, measles, mumps, and chickenpox, are transmitted mainly by large droplets, which explains why outbreaks may take months to run their course in a partially immune population.

Indirect transmission

Indirect transmission covers many diverse mechanisms that have in common only the fact that there can be a delay, often prolonged, in the infectious agent reaching a new host. Indirect transmission is divided into three categories (Table 1). Vehicles are varied nonliving entities, ranging from inanimate objects to water and biological products such as milk, urine, or human tissue on or in which the infectious agent remains in transit to a new host. Personal inanimate objects, such as combs, blankets, and writing materials serving as vehicles for transmission of infective agents, are termed fomites. Many important viruses can be transmitted by fomites, including the agents of measles, chickenpox, and smallpox, but the period in transit cannot be long. Again, the issue is one of survival during exposure to environmental extremes. Because infections known to be transmitted from person to person can also be spread via freshly contaminated fomites, the definition of a contagious disease was extended to include this route, which is sometimes termed 'indirect contact.' Thus, a contagious disease is one transmitted by direct or indirect contact. In reality, contagious agents are transmitted mainly directly, especially by large droplets. Only infrequently are fomites involved,

because this route is a relatively inefficient means of transmission.

Whereas some viruses transmitted by vehicle are spread in water, urine, and milk, this kind of transmission is more common with bacteria that can survive in the environment for prolonged periods. The spread of picornaviruses (Picornaviruses), other enteric viruses (Human enteric RNA viruses: astroviruses, and Human enteric RNA viruses: noroviruses and sapoviruses) and hepatitis A and E viruses (Hepatitis A and E) has been related to exposure to infected water. These viruses, known to be associated with fecal contamination, may be spread not only by drinking water itself but also by ingesting shellfish which filter and concentrate the virus (Hedstrom and Lycke 1964; Portnoy et al. 1975). Transmission from infected urine occurs with a number of the viruses whose primary hosts are sylvatic, such as the arenavirus Machupo (Arenaviruses). Likewise, hantaviruses such as the agents of Korean hemorrhagic fever and the hantavirus pulmonary syndrome (*Bunyaviridae*), recently described in southwestern USA may be transmitted from infected urine or feces (Johnson et al. 1966; Childs et al. 1994). For these, and for other agents similarly transmitted, rodents are the reservoir of infection. They often live close to or in human dwellings and infect humans via their excreta.

Vector transmission is divided into mechanical and biological categories. Mechanical transmission implies that the vector, typically an arthropod, is involved only in providing transport for the agent, i.e. moving it from one site to another without multiplication taking place. This occurs with certain enteric bacteria, in which the pathogen may adhere to the surface of the vector. It rarely takes place with viruses because the agents would be inactivated by the environmental exposure. No multiplication of the agent occurs, so it is not an efficient form of transmission. In contrast, biological transmission is highly efficient. Most of the large group of viruses transmitted by this mechanism were formerly termed the arthropod-borne or arboviruses (Flaviruses; and Togaviruses). They are now divided into different families, such as the flaviviruses and the togaviruses (Westaway et al. 1985a, b). By definition, arboviruses are transmitted by mosquitoes, ticks, or other arthropods, and, in the process, the quantity of virus increases, thus enhancing the probability of infection. Multiplication takes place in the body of the arthropod, and, for example, is released from the salivary glands during a mosquito bite. There has been speculation that nonarboviruses, such as hepatitis B, might be mosquito transmitted, because epidemiological data suggested that distribution was related to mosquito density (Papaevangelou and Kourea-Kremastinou 1974). However, multiplication has never been demonstrated, so the likelihood of a bite producing transmission is low even if infected blood has been taken up (Berquist et al. 1976).

Infected dusts are rarely involved in transmitting viral infections by the airborne route, because desiccation usually inactivates them if they stay exposed to the environment for prolonged periods. Certain respiratory viral infections such as influenza and coxsackie virus A21 are commonly transmitted by small droplets or droplet nuclei (Couch et al. 1966). The droplet nuclei are formed from large droplets as they evaporate while suspended in the air around a spicule of dust. In most cases it has not been possible to demonstrate by air sampling the presence of virus in aerosols, but this mechanism is assumed to operate because of the ability of a virus to infect large numbers. These are the true viral aerosols: the small droplets are able to stay in the air and remain suspended long enough to infect occupants of an entire naval vessel or aircraft with influenza, or to transmit smallpox from one infected person to another through the air-conditioning system of a hospital (Wehrle et al. 1970; Moser et al. 1979). The small droplets also have the ability to reach into the lower respiratory tract, which influences the character of illness that results.

The issue of whether aerosol spread occurs affects control strategies. Natural smallpox was eradicated by ring vaccination, that is, vaccinating those exposed to a case. However, aerosol transmission may rarely occur naturally and could take place in a terrorist incident. The difference in results of mathematical models about how many individuals should be vaccinated in anticipation of an incident is in large part a result of different opinions about how many susceptibles a case can infect (Fauci 2002).

QUANTIFICATION OF CHARACTERISTICS OF VIRAL INFECTION

Infectious dose and secondary attack rate

Epidemiology provides definitions that help to quantify the occurrence of infection and disease in a population. Experimental infection of laboratory animals is always accompanied by quantification; similarly, for work in human infection and disease, quantification is needed. However, because the situation is typically observational and not experimental, different terms and definitions are used. For example, to calculate the infectious dose required to initiate infection in animals, a 50 percent infectious dose (ID_{50}) is determined by inoculation of serial dilutions. Except for certain self-limited infections such as those caused by the rhinoviruses, such experimental studies cannot be carried out in humans (Tyrrell et al. 1960). Even when experimental infection of humans is ethically possible, there are always questions

concerning their comparability with those that occur naturally. Such questions apply to experimental studies of influenza, where large droplet inoculation in the nose does not mimic the aerosol spread of natural infection in which the lower respiratory tract is exposed.

The epidemiological measure historically used to approximate indirectly the infectivity of an agent in humans is the so-called secondary attack rate (SAR). It is more than a measure of infectivity: it describes numerically the communicability of a contagious disease, which is in part related to the ID_{50} of the virus but is also affected by loss of viability during transmission and the susceptibility of the recipient. An index or primary case is identified in a family or other similar semi-closed group. Cases that subsequently occur in the group during the incubation period (the time between inoculation and development of illness) are regarded as secondary; those that occur before are considered co-primary, i.e. a separate introduction into the group. The denominator for the calculation is based on the total number in the group less the index or co-primary cases. Other variations are possible, especially when using laboratory data to identify those truly at risk of infection or illness – i.e. those without prior evidence of infection such as antibody and therefore susceptible to infection. The classic calculation of the SAR is most appropriate for diseases with relatively long incubation periods, such as rubella and mumps. A problem arises with diseases of shorter incubation period (approximately 2–4 days), such as influenza and the common cold, in which it is difficult to distinguish between co-primary and secondary cases because they are only days apart or may overlap. It is possible mathematically to model transmission: if infection rates are known for sufficient numbers of families to be representative of the community, statistical methods can be used to adjust the observed, or so-called apparent, SAR by the probability of acquiring from the community a new infection that had seemed to be a secondary case (Longini et al. 1982). Among infections of high SAR are measles and chickenpox. Rubella is less contagious, thus leaving residual susceptibles among young women entering childbearing age (Sever et al. 1964).

Pathogenicity and virulence

'Pathogenicity' sometimes compares the capacity of different organisms to cause disease, whereas 'virulence' compares the severity of disease caused by different strains of the same organism (see Pathogenesis of viral infections). Here, these terms are specified somewhat differently. In the epidemiological sense, 'pathogenicity' is the proportion of total infections that produce overt disease, which varies from virus to virus and may be affected by host factors (e.g. prior infection with the agent). 'Virulence' here indicates the capacity of a pathogen to produce severe disease. The likelihood of a fatal outcome is calculated as the case-fatality rate or ratio. It is not a true rate, which should cover a specific period, but is in fact a proportion, the denominator being represented by all recognized cases and the numerator by all deaths included in the denominator. Case fatality is high in many hantavirus and filovirus infections; it still is 100 percent in clinical cases of rabies, with rare and often questionable exceptions (Hattwick et al. 1972; Peters et al. 1994). There have been attempts to quantify virulence other than as case fatality, which has the disadvantage of not being a fixed quantity but one that can be reduced in most situations by appropriate treatment. Also, many diseases with the capacity to produce severe illness infrequently cause death; thus the measure is not a good indication of virulence. A persistent problem in quantifying severity is defining exactly what is meant by this term. In contrast, death as an endpoint is unambiguous. Polio is an illustration of the relative independence of pathogenicity and virulence; the disease is potentially very severe or virulent if it occurs, but only 0.1–1 percent of infections are symptomatic. Therefore the virus would be considered of relatively low pathogenicity but of relatively high virulence (Melnick and Ledinko 1951).

OBSERVATIONAL EPIDEMIOLOGY

Viral infections in person, place, and time

Many epidemiological studies of infections involve description of the occurrence of disease and identification of factors that appear to be related to their distribution. Description is the first phase of an epidemiological investigation. It accepts that there is in fact an infection problem and permits development of hypotheses concerning etiology, risk factors, and other variables determining distribution. These relationships may be investigated further in analytical studies. Occurrence of the infectious disease can be described on the basis of a number of criteria. For some conditions, a case definition may be used: a list of signs and symptoms that are required before a case is recognized. Laboratory confirmation may or may not be included in this definition. Sometimes the aim is to identify inapparent infections as well as cases of disease. Here the criteria may be based on laboratory data only, such as virus identification or significant change in antibody titer.

PERSONAL FACTORS

Descriptions of infections or diseases are made in terms of their occurrence in person, place, and time. Whilst temporal, geographical, and personal factors are interrelated, it is useful to examine each separately as a

systematic way of describing the occurrence of an infectious disease. Age is the most important personal determinant of disease because of development and ageing of the immune system, accumulation of exposures over time, and behavioral changes that affect the likelihood of exposure to infectious agents. It is impossible to generalize how age affects pathogenicity or virulence. Hepatitis A and polio are typically mild in young children and become increasingly virulent as children become young adults. Polio emerged as a recognized problem in northern and western Europe only at the end of the nineteenth century. It was called infantile paralysis because it infected mainly the very young, but as time passed it also caused disease in older children. In developing countries the process is being repeated; polio infections often occur in the first 6 months of life, modified by the universal presence of maternal antibody, but the disease is now also present in older children (Nathanson and Martin 1979). Hepatitis A has had a similar progression as the age at the time of infection has changed. In contrast, respiratory viruses such as respiratory syncytial virus (RSV) and parainfluenza produce the most severe disease in young children. In the USA, the median age of infants hospitalized because of RSV is 3 months (Parrott et al. 1973).

The proportion of those infected who develop overt disease also falls with increasing age, in part as the result of repeated exposure to those agents that have the capacity to reinfect with regularity (Monto and Lim 1971). Previous exposures result in a spectrum of outcomes ranging from asymptomatic infection to disease of diminished severity. Other personal factors affecting outcomes of infection are listed in Table 2.

Position in the family affects the occurrence of infections best transmitted in that setting (e.g. the respiratory viruses and enteric agents such as the rotaviruses). An only child in a family will experience lower rates of respiratory infection until other siblings are born (Monto and Ross 1977). Other exposures, such as in day care, may increase the probability of the youngest child acquiring an agent which can then be introduced into and spread within the family (Bartlett et al. 1985). There is evidence that this pattern of occurrence is common with hepatitis A; in fact, community-wide outbreaks of hepatitis A have frequently been traced to day care transmission (Matson et al. 1989). Occupational exposure plays a role in the acquisition of, for example, sylvatic or jungle yellow fever by people working in the forest. The risk from rabies among veterinarians is another type of occupational exposure, but such infections do not result in further dissemination.

FACTORS RELATED TO PLACE

Place of occurrence of viral infection may be related to purely local biological or physical factors. Regional characteristics such as climate and resident flora and fauna determine whether transmission can take place. Most arboviruses are found in specific locations, determined by the distribution of the appropriate vectors or animal hosts. Sometimes the range of a particular agent is quite limited, minor ecological variation producing a niche where transmission can take place. Similarly, agents that are transmitted mainly among animals are limited to the range of that particular animal. Humans are often infected only incidentally, having been in the area where transmission is occurring to the animal hosts or vectors. Infections of animals in which humans are not involved in the major cycle of transmission but are occasionally infected are termed zoonoses.

Other physical or biological environmental factors determine whether common source outbreaks, such as those produced by hepatitis A or E from contaminated water, can occur at a particular location. Generally, special situations in the area, such as sewage outflows or substandard wells are responsible. The presence of an individual in certain locations such as a hospital could result in transmission of hepatitis B in those parts of the world where nosocomial transmission still occurs. In certain areas of Africa where the Ebola virus is present, being in a hospital adds greatly to risk (Baron et al. 1981). Events seemingly associated with place are often equally related to person or to time. Clusters of illnesses are sometimes detected, indicating that transmission of infection is taking place in a particular location. For a cluster to be recognized the transmission must occur over a limited period of time. Such a cluster may involve everyone in that location or may be limited to certain individuals. Reports of clusters are an important alert that unusual transmission is taking place. The first cases of acquired immune deficiency syndrome (AIDS) were detected as simultaneous clusters, in several cities, of a disease producing Kaposi's sarcoma or opportunistic infections in young homosexual men (Gottlieb et al. 1981; Friedman-Kien et al. 1982). The existence of these clusters focused attention on an infectious etiology of the disease, which at the time was thought by some to have other causes such as exposure to environmental toxins or to drugs. HIV transmission was later found to be the explanation.

TEMPORAL FACTORS: CLASSIFICATION OF OUTBREAKS

Time of occurrence may be the most systematically evaluated of the three factors. Much of the terminology used in epidemiology has a temporal component. The terms epidemic, endemic, and sporadic do not have any statistical definitions but simply mean, respectively, occurrence of an infection at a higher than expected frequency, at the expected frequency, or only rarely and in seemingly unconnected fashion. Another term frequently used, also without statistical definition, is pandemic, meaning an epidemic appearing in many geographic locations at about the same time. The term has been used for influenza outbreaks occurring on a global scale following appearance of variants with a new hemagglutinin or a new hemagglutinin and new neuraminidase. It is now appropriately applied to HIV/AIDS which has involved all continents in its inexorable spread (World Health Organization/Global Program on AIDS 1994). The years this has taken contrasts with the months needed for an influenza pandemic to involve the whole world. This contrasting pattern is related to differences in transmission characteristics between HIV, spread by direct contact, and influenza, transmitted by droplet and airborne routes.

The characteristics of outbreaks are described according to the occurrence of cases over time. These characteristics are generally studied by creating an epidemic curve, with cases on the ordinate and time (in days or hours, depending on the speed of development) on the abscissa. Figure 1 shows the pattern of a point source outbreak of Norvovirus infection in which all individuals were exposed at the same time and either became infected and ill with diarrheal disease or remained well (Warner et al. 1991). The group exposed was large (3 000 people) and the attack rate, at 48 percent, was high. The times of onset were divided into 4-h intervals. The suspect meal in question was consumed at noon on Monday; illnesses reported earlier are viewed as baseline cases of diarrhea unrelated to the exposure. Such cases are typical in investigations of a common illness such as gastroenteritis, which can be produced by many agents. The time from the exposure to the peak of the outbreak is the mean incubation period of the pathogen, in this case 40 h. The peak occurred during the 4-h period beginning at 5 a.m., Wednesday.

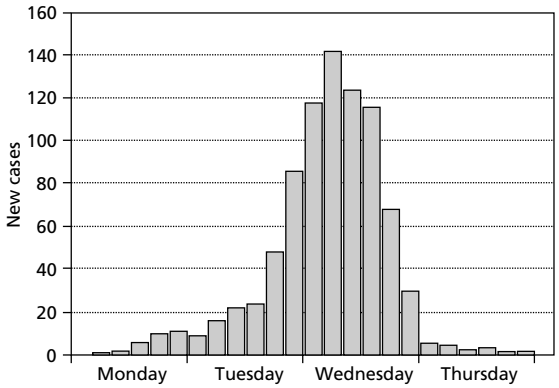

Figure 1 *A point source outbreak of enteritis attributed to Norvovirus after a meal eaten at noon, Monday. Onset of illness (moving means) shown in intervals of 4 h (from Warner et al. 1991).*

If the source remains infectious for a time, the outbreak may continue. The new cases are still being infected from the source and the outbreak may now be better termed common rather than point source. A contaminated well is an example of a common source. With viruses such as hepatitis A or Norwalk-like agents, cases may arise in lower numbers even when the source is no longer infectious. Such continued occurrence is possible only for viruses that can also spread from person to person, a different type of transmission. Pure point source outbreaks assume exposure from one site or at one point in time, the time from exposure to peak being the median incubation period. In contrast, in propagated source outbreaks the infectious agents spread exclusively from person to person. Spread may be by different transmission mechanisms, often large droplet. Even with influenza, which may be transmitted by the more efficient airborne route, one person can infect only two or three individuals, and the outbreak takes 6–10 weeks (or more) to move through a community. It should be remembered that the incubation period of the infection is only 2–4 days, so many generations of spread occur until the outbreak has run its course (Monto and Kioumehr 1975).

Many infectious diseases such as hepatitis A and rubella do not occur at uniform levels in populations but undergo predictable changes in frequency. Certain terms are used to describe these changes. Seasonal variation describes the phenomenon, well recognized with the respiratory viruses, of much higher frequency in colder than in warmer months. Other seasonal variations are less obvious, with rubella generally increasing (before vaccine control) in the spring and hepatitis A in the fall. In temperate zones, transmission of rotavirus takes place almost exclusively during cold weather. Figure 2 shows 5 years of data from the study of young children hospitalized for diarrhea in Washington DC (Brandt et al. 1983). Hospitalizations over all are most common in colder months. Cyclical variation refers to changes of frequency over periods of years, with gradual increases in intensity of transmission. Hepatitis A, for example, has a cycle of 5–7 years. This means that, when intensity of transmission is increasing, illness in the autumn is more frequent than in the previous autumn. The term 'cycle' also implies that there is not only a waxing but also a waning period. In contrast, the term 'secular' is used to indicate long-term trends, which can be unidirectional in nature. The time periods involved must be long, generally more than 10 years.

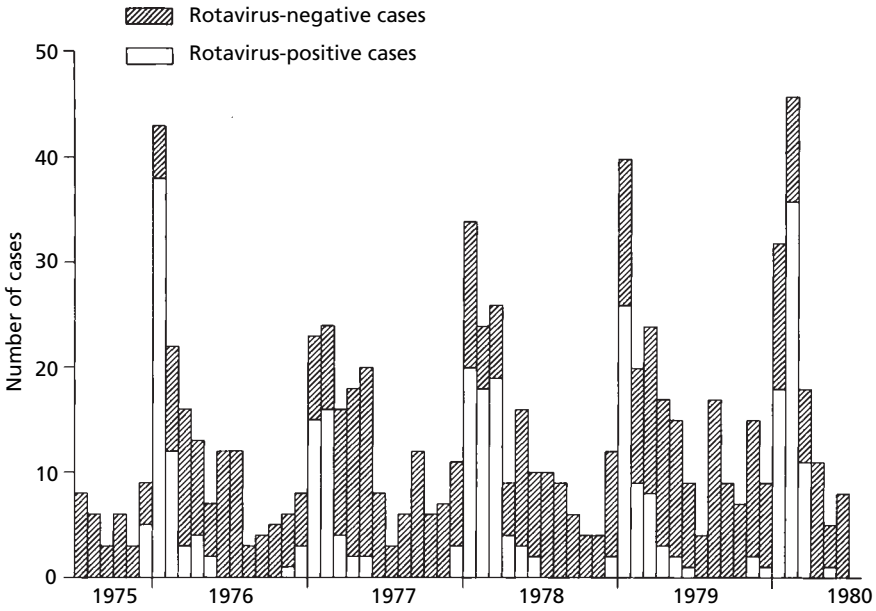

Figure 2 *Distribution by month over a 5-year period of children hospitalized for gastroenteritis and the proportions rotavirus-positive. Children's Hospital National Medical Center, Washington DC (from Brandt et al. 1983).*

Incidence and prevalence

INCIDENCE

Two critical terms used in epidemiology that have temporal definitions are incidence and prevalence. 'Incidence' is the number of new cases of a disease arising during a fixed period in a population of given size; for example, 1 000 or 10 000 individuals. Incidence is sometimes further specified as either a cumulative incidence which expresses incidence as a risk or probability, or as an incidence density which does so as a rate.

These terms, whilst often used interchangeably, provide two types of information (Kleinbaum et al. 1982). Risk is the probability of a disease-free person developing the disease of interest over a defined time and not dying from any other disease during that period. As a probability, risk can have values between zero and one. Risk is measured as cumulative incidence, the proportion of the study population becoming ill in a given period: for example, 'the risk of becoming ill with influenza-like illness in the study population was 12.8/1 000 persons per year.' The need to specify a period can be appreciated by looking at the extreme case of mortality from all causes. If a cohort of 1 000 subjects is followed for 120 years, the risk of dying during this period will be 1 000/1 000 per 120 years. However, during any 1 year of this period, the risk of dying will be much smaller. Thus, when applied to a vectorborne infection, risk of acquiring dengue over a 4-month mosquito season in an endemic area might be 10/100, but only 1.2/100 for a given week. The term attack rate is a cumulative incidence measure used to describe the number in a defined population who become infected or ill during the period of transmission of an agent; for example, the number of children infected with measles in the course of a school outbreak, using the number of susceptible children as the denominator of the proportion. This is more properly termed a risk, and is an example of cumulative incidence. The secondary attack rate, described above, is also an example of such a risk.

In contrast to risk, the incidence rate, sometimes called incidence density, describes the occurrence of new cases in the population per unit of time. Incidence density is most useful for testing epidemiological hypotheses when a long time is needed to follow a cohort to estimate risk, as in most chronic conditions and in some population-based studies of infection. The rate over a period of time is typically estimated using person-time as the denominator of the rate calculation. Person-time is the amount of time each study subject contributes to a study before becoming ill or leaving the study for some reason. Sometimes new individuals may be added to the study population. Figure 3 illustrates the calculation of person-time. Among ten people who were followed over differing periods of time, two cases of disease developed. In the incidence density calculation, eight subjects completed the study, each contributing 12 person-months or a total of 96 person-months. Subjects 3 and 7 contributed 6 and 10 person-months, respectively, before becoming ill. The number of new cases (two) divided by the total number of person-months (112) yields a rate of 2/112 or 1.78/100 person-months. Dividing person-months by 12 would give person-years. Thus, the above translates to a rate of 1.78/8.33 person-months or 21/100 person-years. The same data could be used for an incidence density calculation for ten subjects at risk. The data would give a rate

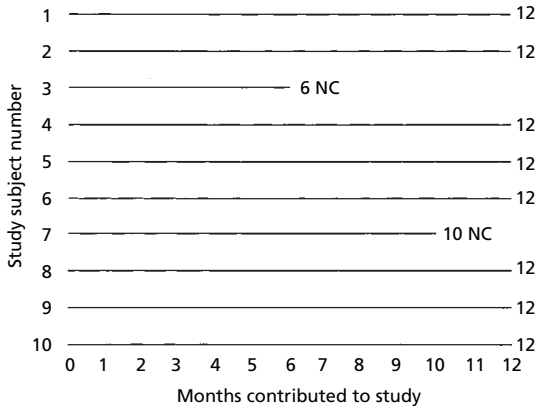

Figure 3 *Hypothetical 1-year study of ten individuals. Two new cases (NC) of disease developed during this period, giving a risk calculation of 2/10 per year and a rate calculation of 2.1/10 person-years.*

of two new cases per ten persons at risk, or 20/100 per year. The differences between the risk and rate calculations, while small, would have been greater with more cases developing or if the study had been carried out for a longer period.

PREVALENCE

The other important term, prevalence, is used less often when dealing with acute illnesses. Most often, the concept is defined as point prevalence, the point here being an arbitrary point in time. In prevalence, it is not new but existing cases that are identified, thus the ideal would be to enumerate them as a simultaneous count. Again the denominator is the population at risk from which the cases are drawn. Enumeration of all cases of AIDS existing in the population of interest at one time, whatever their date of onset, would provide a prevalence rate (Elandt-Johnson 1975).

Prevalence is often used in viral epidemiology when doing serological surveys based on collecting one specimen per person. Serum banks have been established to reflect past experience with infectious diseases in a population. Ideally, the specimens should be representative of the population from which they have been drawn. Antibody present at a specific titer in a population sample collected to represent all age groups will indicate the pattern of past infection. For certain agents, such as arboviruses present intermittently in a geographical area, and for other more common agents such as measles in isolated populations, age-specific prevalence will indicate when infection was last present in that population, the years of birth of the youngest cohort with antibody indicating the last period of spread of the agent (Black 1989). Documenting the occurrence of influenza A subtypes over the last century is another example of use of antibody prevalence. Antibody present in sera, collected before the appearance of a new subtype of type A, has been taken as evidence for the spread of that subtype many years before (Masurel and Marine 1973). When seroepidemiology is carried out with paired sera, change in antibody titer can be sought between two specimens collected from the same individual. The results are the equivalent to incidence, not prevalence, because they indicate that a new infection has occurred in the interval. This is also the case when examining IgM antibody in a single specimen for agents such as hepatitis A, known to produce that antibody for only a short time and thus indicating recent infection.

Monitoring and surveillance

The descriptive variables time, place, and person are employed in monitoring and surveillance of viral disease. For infections that occur regularly the intention is to detect unusual increases. The expected frequency of these conditions, identified either by laboratory tests or on the basis of standard case definitions of illness, can be calculated. An example of the latter involves the use in the USA of reported deaths from pneumonia and influenza (P&I) from 121 cities. The reports are based on a list of specific causes of death, not on the laboratory detection of influenza infection, and are calculated weekly as a proportion of total deaths. Results of the method are shown in Figure 4, with distribution of isolates by type in each of the influenza seasons. The P&I mortality curve has three components: the expected value, the threshold value (1.65 S.D. above the expected) and the actual values observed in the various cities. The expected values are a mathematical expression of past observed values derived from observations of periods without influenza transmission (Serfling 1963). They are higher in winter months than in summer, because of other noninfluenza causes of pneumonia deaths that increase at the same time, such as those caused by primary bacterial infections. As can be seen in Figure 4, in some years the observed mortality considerably exceeds the threshold level for several weeks. Typically, these are years in which there is considerable transmission of type A(H3N2) virus (Eickhoff et al. 1961). In some years (not shown in the figure), excess mortality has also occurred with type B transmission, but this is observed less frequently (Nolan et al. 1980). When examining the data in Figure 4, it is important to realize that the mortality data are the result of clinical diagnoses at the time of death, i.e. without laboratory evidence that the death was related to influenza. Thus the data for laboratory surveillance on which the annual distribution of isolates is based can be viewed as an independent determination. Only influenza produces this characteristic increase in mortality. The phenomenon is remarkable because the data are collected nationally in a country as large as the USA, in which outbreaks do not necessarily occur synchronously in different regions (Glezen et al. 1982). Similar systems

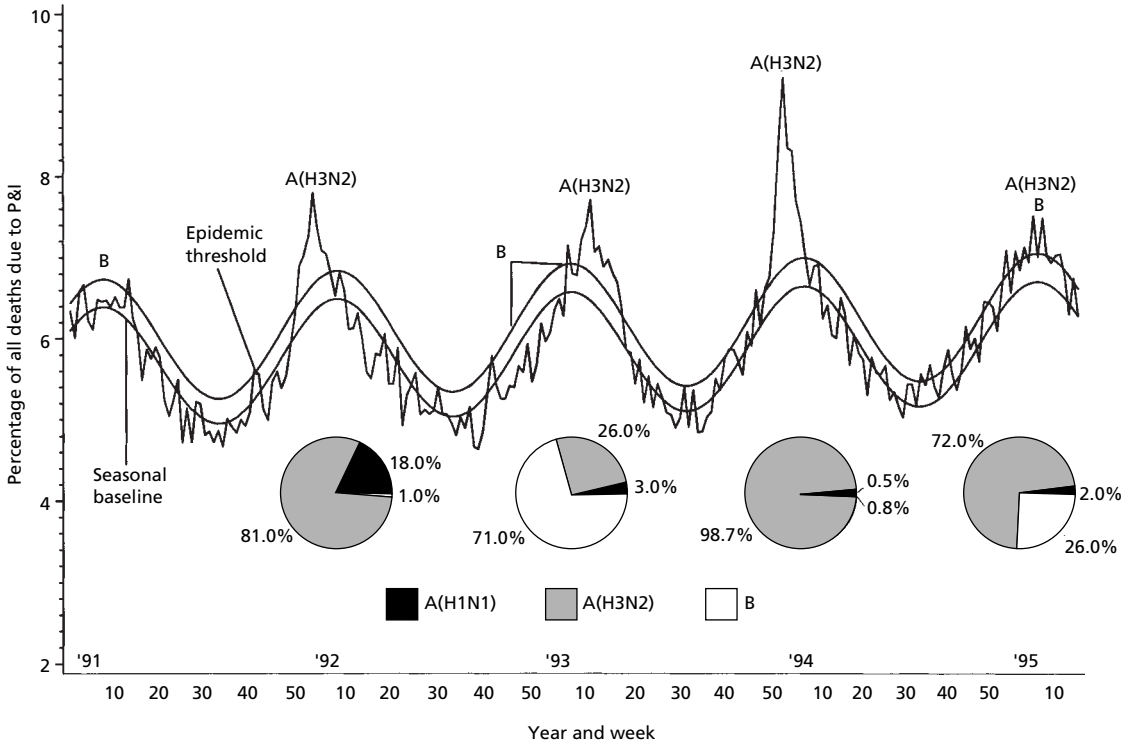

Figure 4 *Data on pneumonia and influenza mortality for 121 US cities, collected by the Centers for Disease Control. The curve indicates the observed mortality data, superimposed on the seasonal baseline and epidemic threshold. Also shown are the distributions of influenza isolates from specimens collected independently during the four seasons.*

are in use in other parts of the world, the data on virus circulation being based on collection of specimens in standard surveillance systems based in physicians' practices (Johnson et al. 1991).

Other diseases only rarely increase in frequency sufficiently to become noticeable in data collected nationally. Most infections are likely to be more localized, and the detection of outbreaks is based on the recognition of the unusual occurrence of cases in time, place or person. Outbreaks are variously defined according to expected occurrence; for some entities a single case may be so unusual as to produce an outbreak investigation. Rabies cases in areas of developed countries where this disease is unusual will be investigated on the basis of a single event. The virus causing hantavirus pulmonary syndrome was recognized and identified as a newly emerging pathogen in southeastern USA on the basis of deaths and severe illnesses clustered in time, place, and, in part, person (Centers for Disease Control 1994). The regional nature of the outbreak contributed to its recognition; had the same number of cases occurred in a wider area, they would have gone unnoticed. As with other similar situations, prospective surveillance initiated after identification of the 'new' virus suggested that it had occurred at low frequency in the past, and that recognition was due to an unusual natural event that produced a cluster of cases; in the case of the hantavirus pulmonary syndrome, the increase in food available for the rodent hosts resulted in their proliferation and an increased likelihood of interfacing with humans. The spread of West Nile virus through much of the United States is an example of a contrary situation. It represented a new introduction into a continent where it had not existed before and was originally recognized because of the clustering of cases. However, the extensive subsequent spread is a result in part because of lack of immunity in the population (Petersen et al. 2002).

Primary analytical methods

CASE–CONTROL STUDIES

The descriptive phases of epidemiological investigations generate hypotheses about factors influencing the occurrence of a disease. Analytical studies then follow, and may involve formal outbreak investigations or more elaborate longitudinal studies. The investigations have in common the use of specific study designs. These designs are divided into case–control and cohort studies. In the first, cases of the disease or outcome being studied are identified and controls without the particular outcome are selected by matching or similar methods to be comparable to the cases in age and other characteristics. Past exposures or risk factors are then examined to determine if they are associated with the disease (Schlesselman 1982). In contrast, in the cohort design indivi-

duals are selected according to characteristics other than presence of the disease or infection of interest. They are followed over time and cases of the disease outcome are observed (Breslow and Day 1987).

Case–control studies can be relatively straightforward in their design and produce results quickly because all the exposures and outcomes have already occurred. The investigation of an outbreak of an infectious disease is generally case–control in nature, one group having the disease and the comparison group not having it. For example, an outbreak of vomiting and diarrhea occurred in a group outing on an American lake where food was served in common and where many had gone swimming (Koopman et al. 1982). Individuals who developed disease according to a case definition were compared with those who did not. The food intake and other exposures of the cases and the controls were then compared. There was no significant difference between cases and controls in terms of foods consumed or other relevant characteristics. However, swimming in the lake, especially with the head submerged, was the risk factor that was more common in those who developed diarrhea compared to those who did not, and the differences were statistically significant. Furthermore, some samples, when available, showed rises in titer for the Norvovirus, suggesting that it was the agent responsible. In this sort of outbreak investigation, the group studied is small. However, it is very important that the cases and controls have similar possibilities of exposure; in this case, people not at the lake would be ineligible.

Larger and more elaborate case–control studies were used to confirm the role of rubella as a cause of congenital anomalies. The original description of clusters of congenital anomalies involving the eyes, and then the heart, ears, and other organs occurring in children whose mothers had experienced rubella in pregnancy allowed development of an etiological hypothesis (Gregg 1941; Swan et al. 1946). The clusters seemed to be related to the epidemic behavior of rubella, since frequency of the abnormality increased cyclically when rubella was widespread (Sever et al. 1965). Many of the initial studies were simply a series of cases. For the analytical studies, cases were children with certain types of abnormalities identified at birth or shortly thereafter and controls were children without abnormalities born in the same locations. Pregnancy histories of mothers of both case and control children were obtained; because rubella and other conditions of interest do not generally result either in a doctor being consulted or in hospitalization, data are generally obtained by interviewing the mothers. This has a disadvantage of introducing potential recall bias: mothers know whether their children had birth defects or were normal and, if the former, are more likely to remember every event that might possibly have been related to the defect (Klemetti and Saxen 1967). Methods can sometimes be developed to try to validate these reported events. If possible, medical or other records collected before the birth are used. By their very nature, case–control studies are nearly always retrospective: cases and controls are identified on the basis of the outcome, and the prior factors determining the development or nondevelopment of the disease are compared. Table 3 lists some of the advantages and disadvantages of the basic study designs. Accurate recall of previous events is an inherent problem with case–control studies because of knowledge of the outcome. The design has other attractive features: it is highly cost efficient, especially for outcomes that are relatively rare. Cases can be gathered easily and, because they have already occurred, the study can be carried out quite quickly. Another inherent problem of the design, however, is the selection of controls. Controls should be similar to the cases in all characteristics except the disease in question. This is often difficult to achieve and questions are always raised about this point. Typically there are two choices of populations from which to draw controls: hospital databases or the community. Each has its own advantages and disadvantages. In the study of infectious diseases, controls must have similar probabilities of exposure to the infections as the cases. In terms of, for example, rubella, cases and controls must have the same opportunity to be exposed and to experience rubella, which varies by both time and place in intensity of transmission. The case–control studies concluded that there was a high level of association between rubella in the first trimester of pregnancy and

Table 3 *Advantages and disadvantages of study designs*

Advantages	Disadvantages
Case–control	
Efficiency – results rapidly available	Selection of comparable controls
Superior for rare outcome	Recall problems
Relatively inexpensive	Validity of recorded data
Cohort studies	
Reduction in potential bias	Duration – may be long
Greater ability to generalize results	Greater expense
No necessity to select healthy comparable controls	Uncertainty of adequate numbers and loss to follow-up
	Rare diseases require large numbers

fetal malformations. That association was very strong and suggested that the risk of fetal malformation was greater than 50 percent in some studies, in one case 80 percent (Pitt 1957; Ingalls et al. 1960) (see also Rubella).

COHORT STUDIES

Cohort studies are generally undertaken after case–control studies indicate the likelihood of an association between a particular exposure and disease outcome. With rubella, these studies began relatively early, because of recognition of biases associated with obtaining histories on the cases. Such investigations are typically prospective in nature, and allow collection of data as new events occur, thus minimizing the possibility of recall bias. However, they must generally be larger with sufficient participants to allow for reasonable numbers of dropouts, and must last long enough to achieve the necessary numbers of events. As a precondition, the outcome of interest must be so frequent that the group followed does not need to be too large or followed for too long. For all these reasons, cohort studies are carried out less frequently than case–control studies because they are more expensive and problematic in terms of producing the required number of observations. However, when feasible, they are powerful evidence for confirming results of case–control studies, as many sources of bias can be avoided and there is not the problem of selecting comparable controls.

In this design the cohort is the population unit selected for study. The only requirement is that the selection cannot be on the basis of disease outcome or anything that might be closely related to the disease. Typically the unit may be individuals in an occupational group, such as nurses or physicians or people living in a certain area. In the case of rubella, two kinds of cohort studies have been carried out (Manson et al. 1960; Sever et al. 1969). In the most powerful design, all children born during specific periods in particular hospitals were studied. Because all children born at the appropriate time were eligible, there was no need to identify controls, and all adverse outcomes of pregnancy could be followed in the cohort. Some mothers would have been exposed to rubella and might therefore give birth to children born with malformations. Most would not.

Another cohort design attempts to minimize the number of nonexposed women who would have to be included. This method identifies an exposure cohort (mother exposed to rubella) and a comparison cohort of mothers not exposed. Note that the selection here is based not on the outcome, congenital abnormalities, as would be the situation in a case–control study, but on exposures, so this remains a cohort study. There is no issue of recall bias because the comparison group is selected on documented lack of exposure. However, it has the potential problem of not being as representative as if all individuals, rather than a selected subgroup, were followed up. Estimates of the risk of maternal rubella in the first trimester in producing malformations was as low as 7–17 percent in some cohort studies, although others felt that, depending on length of follow-up and definitions used it might actually be higher (Jackson and Fisch 1958; Lundstrom 1962). This reduction in risk estimation had public health implications before the vaccine era, because pregnancies were often terminated after maternal rubella. From an epidemiological standpoint, cohort studies are better than case–control studies in providing data and results that can be generalized to the population of interest so that appropriate decisions can be made.

OTHER USES OF ANALYTICAL STUDIES

Although vaccines are usually evaluated by randomized controlled trials, an experimental study design involving an intervention, observational designs can also be employed successfully to evaluate the effectiveness of vaccines. The term ‘efficacy’ is generally employed for results of randomized trials; ‘effectiveness’ is used to indicate the results of observations when the intervention is in general use, especially when the outcome is not a laboratory-confirmed infection but a clinical diagnosis. The latter sort of study is the only type possible when, as is the case in North America for influenza vaccine for the elderly, ethical considerations preclude use of a placebo and questions still exist as to the value of the preparation. The observational design does not require that vaccine be denied to part of the group, as would be the case if a placebo were employed. The purpose of using inactivated influenza vaccine in older people is to prevent serious complications of the disease, especially those requiring hospitalization. However, unless a large population can be followed, these hospitalizations do not occur sufficiently often to allow the use of the cohort design. For this reason, two multi-year case–control studies were carried out, one in the USA and the other in Canada (Foster et al. 1992; Fedson et al. 1993; Ohmit and Monto 1995). The exact designs varied, but in both cases the influenza season was identified and possible influenza complications were defined from hospital records. Recognizing the need for generalization of results, both studies were designed to select their controls not from hospitals but from comparable community residents. In both, the vaccine was found to be significantly effective in preventing hospitalization, and, in the Canadian study, in preventing deaths in the influenza seasons coded as being related to respiratory diseases. Another study used a cohort design to confirm these findings (Nichol et al. 1994). As expected, many people needed to be followed up. The effectiveness of the vaccine was comparable with that in the previous case–control investigations. That several differently designed nonexperimental studies came to similar

conclusions is convincing evidence that the results in a single investigation were not simply a chance occurrence.

Observational studies to confirm etiology

Koch's postulates in their various forms were the first systematic approach for determining that a pathogen caused a disease (Rivers 1937). They were formulated after early observations that simply isolating an agent from an individual with a particular disease did not necessarily mean that the agent caused that disease. The postulates were based on experiments, provided that disease could be reproduced in laboratory animals. They did not allow for asymptomatic infection because they stated that the agent should always produce disease. They also assumed that the potential pathogen had a unique role in producing a disease: only one hepatitis virus could produce hepatitis. We now know that clinical syndromes can frequently be caused by a variety of agents and that clinical manifestations of infection vary greatly in terms of age and other factors, so it might not seem that the same pathogen was involved. In addition, many viruses may not infect experimental animals at all or, if they do, will not produce diseases comparable to those in humans. For this reason, Koch's postulates have been complemented (or modified) by epidemiological studies, usually observational, to confirm etiology. Typically, case–control designs are used, because they are easy to carry out and require smaller numbers of observations. Studies of this sort are particularly necessary when dealing with agents that produce chronic infections.

Another problem occurs when a potential pathogen is shed for prolonged periods from people who have had an illness in the past, or after an asymptomatic infection. Agents may be isolated from individuals who develop another illness, and thought, incorrectly, to cause the current instead of the preceding illness. This misconception can occur with the herpesviruses. At the very least, an agent must be identified significantly more frequently in cases with the disease than in comparable controls. This analytical design assumes that asymptomatic or chronic infection will occur and that some controls will be virus positive, but not as frequently as cases. Etiological association of infectious mononucleosis with Epstein–Barr virus (EBV) was difficult to accomplish, because of continuing shedding of the virus (Hallee et al. 1974). Even more difficult has been the demonstration of the association of hepatitis B virus with primary hepatocellular carcinoma, because of the long period between infection and development of the disease (Beasley 1982).

When observational approaches, rather than experimentation, are used to demonstrate etiology, additional standards are generally applied to assist in deciding that there is a statistically significant etiological relationship between a disease and an agent or other potential precipitation factor. These standards were developed to evaluate the relationship between environmental exposure and chronic diseases, specifically cigarette smoking and lung cancer. They apply equally to viral infection (Hill 1965). There must always be a proper temporal relationship: the putative etiological factor is present before the disease occurs. This point is not particularly difficult to understand; in fact, there is often a tendency to assume an etiological role on the basis of a simple temporal relationship. It is further required that the etiological agent must have a scientifically logical role in the disease it is thought to cause. In other words, hepatitis B virus has a logical role in producing chronic liver disease, whereas it would be difficult to hypothesize such a role for the influenza virus. Strength of the association is also critical; i.e. if the associations are strongly statistically significant, an etiological role is more likely. Most critical, as illustrated by the examples given above, is reproducibility of results. Consistent results from different study designs are strong evidence of an etiological association.

The road to demonstrating etiology involves an initial hypothesis and a series of studies. Such a road can be followed in the demonstration in North America of the role of aspirin in the production of Reye's syndrome. The syndrome is a combination of encephalopathy and acute liver abnormalities involving mitochondrial damage. It was recognized for many years to be an unusual complication of various infections, mainly influenza and chickenpox, occurring a few days after the acute illness. Why it happened in a small proportion of infected children was unknown. Descriptive studies suggested that aspirin ingestion might be involved, but this notion was rejected by many investigators because of lack of a clear dose–response relationship (Starko et al. 1982). However, the characteristics of aspirin intoxication provided a credible scientific basis for the relationship. A series of independent case–control studies demonstrated such a statistically strong and consistent role for aspirin that the last study was suspended in the pilot phase and an educational program was begun (Halpin et al. 1982; Waldman et al. 1982; Hurwitz et al. 1985). Cohort studies were not carried out because Reye's syndrome was too rare to allow use of that design and the associations in the case–control studies were so strong.

EXPERIMENTAL EPIDEMIOLOGY

Simulations

Although most contributions of epidemiology to our understanding of viral infections are observational, experimental approaches are often useful in understanding relationships not defined by other methods. Two will be considered: one involving actual interventions and the other involving simulations. The latter

method has mainly been applied to modeling transmission and epidemics mathematically and identifying the effects of various interventions that might be used to prevent or interrupt the outbreaks of infection. Mathematical models have evolved from rather simple approaches ranging from the use of balls to simulate individuals (Monte Carlo models) to elaborate computer structures designed to resemble a community with families and schools that mix with each other. The two basic types are deterministic models, which use differential equations, and stochastic models, which use random number generation to approximate the manner in which events take place naturally (Abbey 1952; Bailey 1957). The latter type of simulation is now easier with use of powerful computers so that many replications can be carried out. One of the first infections to be studied with these methods was influenza. Simulations were performed to determine the effects of, for example, vaccinating school age children with influenza vaccine (Elveback et al. 1976; Longini et al. 1977). As demonstrated in one experiment, vaccination of school age children increased immunity, sometimes termed herd immunity, in the segment of the population most responsible for introducing the virus into families and spreading it in the community (Monto et al. 1970). The result was not only protection of the vaccinated children but also interruption of transmission, which indirectly protected the rest of the community. Simulation modeling has also been applied to HIV transmission and AIDS forecasting, and has been particularly valuable, given the long-term nature of the infection and the difficulty in predicting spread (Hethcote et al. 1991). Most recently, it has been especially useful in assessing the effects that vaccination could have on the future occurrence of the disease.

Controlled trials

The most accepted intervention study in infectious disease epidemiology is the randomized controlled trial. Traditionally, the intervention has been vaccination, although more recently antivirals have frequently been studied. Methods for randomized clinical trials have been the subject of a number of reviews and comments, and the many issues and approaches will not be discussed here (Spilker 1991). The endpoint for acute illnesses is generally prevention of the disease. The efficacy of hepatitis B vaccine was evaluated by antibody production and prevention of acute disease in populations of homosexual males (Szmuness et al. 1975). The design was a randomized, controlled trial. The group chosen for study was at high risk of infection and the study could be concluded in a short period of time. Potentially eligible participants were screened and only those without antibody were included. The frequencies of infection and disease at various periods after vaccination were compared in those who received the active preparation and those who received placebo. The results demonstrated the value of this vaccine in primary prevention. In addition to protecting against acute infection in adults living in developed countries, the vaccine is now used in developing countries, not only to prevent the acute illness but mainly to prevent primary hepatocellular carcinoma. If this tumor decreases in frequency as a result of vaccination, it will be ultimate proof of etiology. Similarly, with Reye's syndrome, education about the role of aspirin in the disease resulted in decreased use. Reye's syndrome has nearly disappeared in areas where it was previously common, adding further evidence for an etiological connection (Remington et al. 1986). Certain potential etiological relationships have bedeviled investigators for many years. It was thought that certain viral infections trigger attacks of asthma in sensitive children. The data are better for children than for adults, and, in both, rhinoviruses seem to be the virus most frequently involved (Mcintosh et al. 1973; Minor et al. 1974). Development of PCR techniques which can identify rhinoviruses which cannot be cultivated has helped to document this relationship (Johnston et al. 1995a). A similar situation applies to triggering exacerbations of chronic respiratory disease in the elderly although the relationship here is more tenuous. If use of an antiviral to prevent or treat rhinoviral infection also reduces episodes of the chronic condition, it would be the final demonstration of an etiological relationship.

EPIDEMIOLOGICAL CHARACTERISTICS OF RESPIRATORY VIRUSES

Causes of common respiratory illnesses

Many viruses are responsible for the bulk of respiratory infections. Although the agents are very different from a virological standpoint, they do share epidemiological characteristics. Being surface infections, they do not produce long-lasting immunity. Instead they have the capacity to reinfect, even without antigenic change (Glezen et al. 1986). Other than influenza (Orthomyxoviruses: influenza), which can produce severe disease in older children and adults, some viruses such as parainfluenza and RSV (see Respiroviruses: parainfluenza virus), may cause severe disease in infants and young children on initial infection and mild or inapparent infection indistinguishable from the common cold in older people. Thus, older siblings who introduce a particular infection to the family may contract a mild illness, while the younger child may experience bronchiolitis or pneumonia. RSV is the principal cause of severe lower respiratory illness in young children. The mean age for hospitalization, which occurs in a small proportion of infected children, is 3 months

(Parrott et al. 1973). This early age of onset prompted the hypothesis, later proven to be incorrect, that maternal antibody, which is always present to this ubiquitous virus, is responsible for the pathogenesis of the disease. It has now been shown that children born with the highest titers of maternal antibody are those least likely to develop severe disease (Glezen et al. 1981). As a result, maternal immunization is being examined as a way of modifying the initial infantile infection and the use of immune globulin is being examined for prophylaxis and treatment. Parainfluenza virus types 1 and 2 are the major agents of laryngotracheobronchitis (croup). The peak age for these initial, recognizable infections is later than that for RSV, and the protective effect of maternal antibody was never in doubt (Monto 1973).

Rhinoviruses (Picornaviruses) and coronaviruses (Coronaviruses, toroviruses, and arteriviruses), in contrast to RSV and parainfluenzaviruses, produce only coldlike symptoms regardless of whether they infect children or adults. Rhinoviruses, as the principal agents of the common cold, infect individuals many times throughout life. Even in the first years of age, when attention is usually directed to the other agents that may produce lower respiratory infection, the rhinoviruses are more commonly isolated (Monto et al. 1986). Data on the annual incidence of respiratory infections due to all causes were collected from residents of the small community of Tecumseh, Michigan (Monto and Sullivan 1993). These data are shown as curves in Figure 5, with results arranged by gender. As can be seen, there is a suggestion of sparing of infants aged <1 year, because of the presence of maternal antibody. Thereafter the frequencies fall off with increasing age, rising again in young adulthood when individuals start their families and are exposed to young children. The higher frequency of illnesses in females as compared to males is well recognized. In women who work outside the home, the frequency of illness in those aged 20–34 years is higher than in those who do not. Thus continual exposure to children must be a major factor. The age-specific frequency of rhinoviruses roughly parallels these curves. This similarity is a result of the major role of rhinoviruses in the etiology of the common cold and other frequent respiratory illnesses (Monto et al. 1987). Coronaviruses are responsible for illnesses similar to those caused by rhinoviruses. Because they are difficult to isolate and occur much less frequently than the rhinoviruses, much less information is available on their occurrence in populations. Newer tests involving antigen detection may increase our knowledge of their behavior and distribution (MacNaughton 1982).

Respiratory virus infections differ in their seasonality (Monto and Sullivan 1993). Although, overall, viral respiratory infections increase in frequency in cold weather in many geographic areas, isolation of rhinoviruses peaks in the period after schools reopen: children come into contact with each other for long periods and can spread these viruses that require relatively close contact for transmission. Rhinoviruses account for most of the respiratory illnesses in the community at that time. In other geographic areas, although the autumn peak is prominent, another peak of infection in the spring is also recognized (Hendley et al. 1969). Other respiratory viruses have different periods of spread in different regions. In many areas, RSV transmission peaks in winter or early spring and parainfluenza virus in spring and late autumn, the exact occurrence varying by place and by year. Outside the temperate zones, periods of activity are different and must be defined locally. Because person-to-person transmission is always involved, the agents take weeks to move through even a small community.

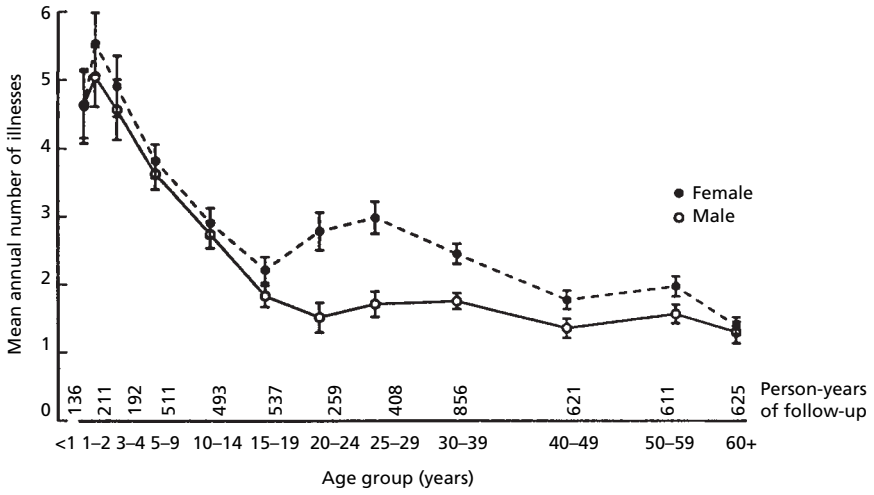

Figure 5 *Mean number of respiratory illnesses per person-year (95 percent confidence intervals) in males and females living in Tecumseh, Michigan (from Monto and Sullivan 1993).*

INFLUENZA

Influenza (Orthomyxoviruses: influenza) is potentially serious in all individuals who develop disease. Infection rates are highest in children and adults who are sufficiently ill to seek medical advice (Monto et al. 1985). However, the elderly and those with chronic illnesses experience the most severe disease, often with complications such as pneumonia (Chin et al. 1960). Reasons for the susceptibility of older individuals are varied, and probably related to depressed cell-mediated immunity (Phair et al. 1978). Because of the danger of illness in older people and those with chronic conditions, vaccination programs in many countries are not intended to prevent infection in the young. Rather, older people are vaccinated as a means of preventing hospitalization or death. As a result, disease in the young, who sustain the major burden of a complicated infection, is not affected, and outbreaks continue. An exception is Japan, where a former policy was designed to limit spread by vaccinating school-age children (Dowdle et al. 1980).

Influenza, like other respiratory agents, is seasonal, no obvious transmission taking place in warmer months of the year in the temperate zones, although asymptomatic infections have been detected serologically, particularly with type A viruses. Outbreaks of influenza in cold seasons can be recognized by various indicators, including increased visits to physicians or school absenteeism. These indicators can be found during major outbreaks of all types and subtypes of influenza; they are a reflection of the high infection frequency in the general population. Transmission of influenza types A(H3N2) and B can also be detected by the ability of these viruses to be fatal in older people and those with high risk conditions. Such deaths, as complications of the primary viral infection, generally occur 2 weeks after the initial episode, so excess mortality is a delayed indication of transmission.

Although seasonal outbreaks of influenza may be caused by one viral type or subtype, mixed or sequential outbreaks of different types may also occur. The viruses appear at various other times in tropical climates, either throughout the year or during the rainy season, and such regions are likely to be the source of new strains. Pandemics of type A influenza take place at irregular intervals following sudden changes in the viral hemagglutinin or the neuraminidase, or both ('antigenic shift'). For a time, it was thought that new viruses with pandemic potential emerged at regular intervals, approximately every 10 years. In retrospect, these conclusions were based on confusion concerning whether a shift in surface antigens had occurred during the period 1918–1956, and observations during only a limited period thereafter. It had always been assumed that, when a type A strain with new surface antigen or antigens emerged, it would totally replace the previous A subtype. In 1977, the A(H1N1) subtype reappeared 20 years after it had been completely replaced in 1957 by type A(H2N2). The type A(H3N2) viruses have been circulating since 1968 and, instead of replacing these viruses, both subtypes have co-circulated since that time. Type A(H1N1) has largely been restricted to the younger segment of the population and type A(H3N2) has occurred in all age groups (Masurel 1976; Kendal et al. 1977).

When pandemics of influenza have followed a shift in type A antigens, the same age-specific morbidity and mortality patterns have been observed as in the annual epidemics of influenza but at much higher frequency. However, in 1918, the pandemic viruses thought, on the basis of serological epidemiology, to be related to swine influenza, produced unusually high mortality in young adults, a group usually experiencing significant morbidity, but little mortality. At least 20 million people died worldwide during this pandemic, which is still a unique and unexplained event, possibly related to unusual bacterial superinfections (Shope 1936). Even with the identification of the hemagglutinin of the 1918 virus, reasons for its higher pathogenesis have not emerged (Taubenberger et al. 1997). Recent pandemic strains of influenza first caused outbreaks of disease in humans in southern China. There, the combination of high population density and animals, especially domestic ducks and pigs, living in close contact with humans, often in the same dwellings, might have been responsible (Kawaoka et al. 1993). Many domestic animals have their own type A influenza viruses, but such infections are not true zoonoses because these viruses are not pathogenic for humans. A recent exception was the spread in Hong Kong of A(H5N1) virus from chickens to humans (Subbarao et al. 1998; Claas et al. 1998).

New pandemic viruses seem to result from reassortment made possible by the segmented genome of the influenza virus. The gene segments coding for the surface antigens of the animal strains replace the comparable segments of the strains pathogenic for humans. The result is a new virus with internal components from the old pathogenic virus but with new hemagglutinin and sometimes a new neuraminidase from the animal strain. Type B influenza viruses do not infect animals, and pandemics of type B do not occur, strengthening the hypothesis of the animal origin of pandemic type A variants. Thus, the only changes seen with type B viruses are gradual year-to-year variations, referred to as 'antigenic drift.' The same drift also occurs with type A strains over the years, in addition to the episodic shift associated with pandemics. This regular drift makes it necessary to incorporate fresh strains in the vaccine, because efficacy drops if there is not a good match between circulating variants and in the vaccine strains. Updating is usually done annually with type A(H3N2) and not as often with type A(H1N1) and type B viruses, reflecting more rapid changes in type A(H3N2).

VIRUSES INFECTING THE GASTROINTESTINAL TRACT

Agents of diarrheal disease

Diarrheal disease in industrialized countries is of varied etiology. Unlike respiratory illnesses, in which viruses are the principal pathogens, enteric illnesses are sometimes of bacterial or parasitic origin, especially when they occur as outbreaks. Much of the disease that occurs more regularly in families is of viral origin and its frequency increases in the cold season, reflecting greater opportunities for transmission (Monto and Koopman 1980). Rotaviruses are the main cause of dehydrating diarrheal disease in young children throughout the world (see Rotaviruses). Although infants and young children in developing countries may die of these infections if they are not rehydrated with salt-containing solutions (orally or sometimes intravenously), the disease is rarely so severe in the developed world, mainly because of such factors as better nutrition (Black et al. 1981). These are surface infections that recur throughout life. Whilst initial infections in infants may be severe, re-infections usually produce mild illness or asymptomatic infection. As with the respiratory viruses, this has implications for spread within families.

Paradoxically, the pattern of occurrence of rotavirus infection is more like that of the respiratory viruses than of other enteric agents, although transmission clearly takes place by the fecal–oral route; whereas large amounts of virus are shed in the stools, none has been detected in the upper respiratory tract. As with respiratory viruses it is possible to examine the role of the family and the community in determining the occurrence of infection. All rotavirus types are seasonal in the temperate zones, most illness occurring in the colder months (Brandt et al. 1982; Vesikari et al. 1992). Rotavirus vaccines, prepared from live-attenuated strains, have been and continue to be developed for use in infants (see Rotaviruses). Because of the need for multiple types, there has been at least a potential problem with interference, a phenomenon common to live attenuated vaccines, with difficulty in producing immunity simultaneously to several types. The purpose of vaccination is not necessarily to prevent infection or illness completely, but to render it more like re-infection, thus preventing severe dehydration.

Rotaviruses are responsible for only some of the enteric illnesses experienced in the community during the cold season. Identifying the etiological agents of other common illnesses has been complicated by the difficulty or impossibility of growing many of them in cell culture. Norvovirus, now recognized to be a calicivirus, is one of a group of viruses causing water-related outbreaks (see Human enteric RNA viruses: norvoviruses and sapoviruses). A variety of exposures are involved, including drinking and swimming in water containing the virus, especially when the head is submerged; contaminated seafood has also been implicated (Gunn et al. 1980; Kaplan et al. 1982). Person-to-person transmission also occurs, increasing the potential for spread in families and the community.

Immune electron microscopy was the basic method for identifying rise in antibody titer and reagents had to be prepared by inoculating human volunteers (Herrmann et al. 1985).

The recent cloning of the Norwalk agent will allow better understanding of its epidemiology as reagents become available for testing sera. Similarly the enteric adenoviruses, types 40 and 41, originally detected only by electron microscopy can now be identified by enzyme immunoassay (EIA) (Johansson et al. 1985). The association of these viruses with enteric disease in infants is an example of use of the case–control design. The respiratory adenoviruses, which could at that time be easily cultivated in cell culture, were isolated in equal numbers from the stools of cases (children hospitalized with diarrhea) and controls (children hospitalized with other conditions). However, adenoviruses that could not be cultivated in routine cell cultures were significantly more commonly detected in children with disease than in controls (Brandt et al. 1985). It has been suggested that an autumnal increase in enteric illness is related to these adenoviruses, but such seasonality could not be demonstrated in hospital-based studies.

Polio and enteric hepatitis viruses

The enteroviruses are generally transmitted by the fecal–oral route. Some exceptions exist, however, such as coxsackie virus A21, an unusual cause of respiratory infection that can spread by aerosol. The dynamics and characteristics of this infection were well studied in the military, in whom it had presented an occasional problem. Polio is the best known of the enteroviruses, producing a potentially serious disease in a small proportion of those infected. Global elimination of polio is underway, by use of the live-attenuated vaccine administered universally and repeatedly to young children. The method is based on the known transmission pattern of the vaccine virus, which resembles that of the wild virus in being shed in large quantities and for long periods in the stool of inoculated children (Hull et al. 1994). The shed virus can be transmitted to contacts, especially other children, and to adults in the family. By inoculating children regularly (annually or more frequently) as part of a mass vaccination program, it is possible to spread the vaccine viruses in the environment so that children who are missed by the vaccine program are indirectly exposed to them. This approach, which combines herd immunity, or increasing the level of antibody in a population so that susceptibles are rare

and transmission is interrupted, together with the special characteristics of transmissibility of the live polio vaccine, has resulted in the elimination of transmission of wild polio virus in the Americas. The procedure is now being applied in other parts of the developing world (Centers for Disease Control 1995).

Hepatitis A is classified as an enterovirus; it shares epidemiological characteristics with other enteroviruses but is unusual in having a relatively long incubation period (median 28 days) (Lemon 1985). Spread in the developed countries typically occurs from person to person in the family or in settings such as day care centers for children, especially when they are not toilet trained. Much of the infection in North America has been traced to these day care outbreaks, from which spread continues in families and older individuals (Hadler and McFarland 1986). In developing countries and in special situations in the industrialized world, spread can often occur through contaminated water or by consuming uncooked shellfish from contaminated waters. Other food transmission is possible whenever there is fecal contamination. In the developing world, infection occurs at an early age and is often asymptomatic. In the industrialized countries, infection is delayed and often will not occur at all, rendering much of the population susceptible if exposed. Travelers to developing countries generally do not have protective antibodies from past exposure, and are thus at increased risk. One solution, before vaccine became available, was use of immune globulin, which gives temporary protection. There are now vaccines that can protect individuals from developed countries who will be exposed in the developing world. Such infection has been a major risk, especially for people exposed for long periods in areas with poor standards of hygiene (Wagner et al. 1993). Hepatitis E has epidemiological characteristics similar to those of hepatitis A, and increasing availability of reagents will allow better understanding of its behavior in populations. Some outbreaks of disease thought to be due to hepatitis A are now recognized to have been, in all probability, caused by hepatitis E (Wong et al. 1980).

VIRAL INFECTIONS WITH BLOODBORNE TRANSMISSION

Hepatitis B and related viruses

Hepatitis B was, before the discovery of HIV, the most extensively studied bloodborne pathogen. During the course of many viral infections, there is often a phase of viremia; however, bloodborne transmission is unlikely when viremia lasts for only a period of hours. The probability of such transmission is increased when viremia persists for days or, as is the case with some infected with hepatitis B, for years. The likelihood that infection will persist decreases with increasing age at time of exposure. Thus, perinatal infection is most likely to result in chronic viremia. The transmission of hepatitis B by blood or blood products was documented well before the virus or its antigens were identified (Sawyer et al. 1944). During the Second World War, yellow fever vaccine used by the US military was stabilized by the addition of human albumin. Those who received the vaccine developed hepatitis and, by epidemiological evidence, it became clear that it was contaminated by what is now known to be hepatitis B virus. On initial study, the cases of hepatitis that were detected did not seem to bear any temporal relationship to an exposure to persons with infection or to a common event. Then it was realized that vaccination might be the common source. Because vaccinations had been administered over a long period, cases were occurring in an apparently unrelated fashion. Plotting of duration since vaccination resulted in a typical epidemic curve, with cases distributed around the long median incubation period of approximately 120 days from exposure.

Hepatitis B is transmissible not only through blood and blood products but also through sexual contact. Simply living in a family with an infected person slightly increases the probability of transmission. It is not clear exactly how this occurs. The virus is present in various body fluids, in addition to blood and semen (Irwin et al. 1975). Transmission requires only very small amounts of blood, so leakage through minor abrasions and tears may be responsible. Hepatitis B was known to be more common in certain professional groups such as dentists, almost certainly because of exposure to small amounts of infected blood commonly lost in dental procedures rather than through virus present in saliva (Mosley et al. 1975). It was especially common among homosexual men, especially those with multiple partners. In fact, the trial of hepatitis B vaccine was conducted in uninfected sexually active homosexual men, because exposure was predictable (Szmuness et al. 1980). The transmission was clearly sexual, but how much of it involved transfer of small quantities of highly infectious blood and how much other infected bodily fluids was difficult to quantify. Various specific sexual practices such as anal intercourse were identified as risk factors even before the study of HIV transmission (Szmuness et al. 1975).

A particular problem with hepatitis B, especially in eastern Asia (including China) and in sub-Saharan Africa, is that transmission is mainly vertical and children become infected at birth from transplacental and direct exposure to maternal blood (Stevens et al. 1975). When infection occurs at this age, it is likely to persist, and thus may be carried to the next generation. Hepatitis C shares many features with hepatitis B, including its transmission by blood and blood products. Risk groups differ somewhat with, for example, less sexual transmission (Alter et al. 1989).

Human immunodeficiency virus

When human immunodeficiency virus (HIV) was first described, its epidemiology was found to be remarkably similar to that of hepatitis B (see Hepatitis B). Differences are related to the natural history of the disease and to the far lower transmissibility of HIV under most conditions. A persistently high level of viremia allows hepatitis B virus transmission to occur with relative ease for long periods. In contrast, transmission of HIV is most likely early in the infectious process when there is viremia of high titer, or later in the development of AIDS itself when the level of viremia increases again. The early period is probably the most important for transmission, because at that time individuals may not know they are infected and remain sexually active (Jacquez et al. 1994). Because of its importance, the epidemiology of HIV has been studied intensively over the period since the virus was identified and many characteristics of its distribution are now well established. Much attention has been given to the role that various behaviours play in transmission, since, in the developed countries, antibody tests have ensured that blood and blood products are safe and transmission by that route of infection no longer occurs. Among homosexual men, receptive anal intercourse is the prime risk factor, but other sexual practices are possibly to blame, if not nearly as risky. Heterosexual intercourse can also transmit the virus efficiently, but male-to-female transmission is accomplished more easily than the reverse (Padian et al. 1991). As with hepatitis B, injecting drug use appears to be an independent risk factor for transmission. Transmission also occurs through breast milk and artificial insemination. In one controversial case, the argument for transmission of virus to the patients of an HIV-infected dentist was strengthened by the similarity of the viral nucleic acids in the various cases, a technique sometimes referred to as molecular epidemiology (Crandall 1995).

In the developed countries, the disease has predominantly been one of males, both homosexual and bisexual men and injecting drug users. Heterosexual transmission has often involved sexual partners of these individuals. In the USA, African-Americans and other minority groups are increasingly involved. In developing countries, the male to female ratio often is 1:1, and the prevalence of infection in the general population, especially in certain countries of Africa, is high. The infection has entered south and southeast Asia, where transmission has been rapid. Mathematical epidemiology has been used to study the relative probability of different transmission mechanisms when several may be involved, and to predict the course of the pandemic. Simulations have been particularly valuable in trying to understand how altering transmission by vaccination or behavior modification will affect the course of the epidemic in different regions.

ZOONOSES AND VECTORBORNE INFECTION

Zoonoses not involving arthropods

Many, but not all, of the vectorborne viral infections are also zoonoses and are discussed together. The zoonoses are human infections in which the principal reservoirs of the viral agent are wild and domestic mammals, birds, and possibly other species such as reptiles. Cycles of infection can be maintained in these reservoirs without the involvement of humans, in whom infection occurs incidentally. Zoonoses not involving arthropod-vector transmission are listed in Table 4, with animal reservoir and route transmission. Rabies (see Rhabdoviruses: rabies) is an example of a zoonosis not involving vectors. In most of the world, rabies is widely distributed in a variety of mammals, the predominant species varying from region to region. In North America, foxes, skunks, and raccoons are mainly involved (Anderson et al. 1984). Of these, only raccoons frequently invade human habitations but in most cases transmission remains within the particular species. Transmission sometimes involves domestic animals such as dogs or cats, who, because of their activities outside the home, will occasionally come in contact with the wildlife hosts. Insectivorous bats also maintain rabies in their own colonies but, because they often live in human dwellings, direct transmission to humans occasionally occurs. Vaccination of domestic pets is used to create a barrier between wildlife rabies and humans; it is highly effective, with the possible exception of preventing direct bat transmission. There have been several years in the USA without a single case of human rabies, even though extensive transmission in animals still occurs. In other parts of the developed world, the species involved in maintaining wildlife rabies differ. In Europe, foxes are often involved, and attempts are now being made to control transmission in these hosts by drops of baited food containing vaccine (Brochier et al. 1991). This is possible only when the geographic areas are relatively limited. In remote areas, many more species are involved and control is impractical.

Some parts of the world, typically islands such as Great Britain and Hawaii, are rabiesfree; because potential hosts are present in the wild, exclusion of animals who might be responsible for importation is a critical part of control activity. In many developing countries, rabies of domestic animals is common, especially of dogs which are barely domesticated and often form feral packs. Transmission from dog to dog does occur, as well as from dog to humans. This is in contrast to the typical situation in the developed world, where the dog, as well as humans who become infected, are ‘dead-end hosts’; that is, they are generally not responsible for any further transmission. The few human cases that occur in indus-

Table 4 *Zoonotic viral infections without arthropod transmission*

	Virus and disease	Animal reservoir	Mode of transfer
Rhabdoviruses	Rabies virus	Foxes, skunks, bats, raccoons, mongooses, dogs, cats, etc.	Bite. Possibly saliva through abraded skin or airborne
Arenaviruses	Lymphocytic choriomeningitis virus	*Mus musculus*	Contact with urine, feces or other infected fluids. Rarely person-to-person or nosocomial spread. Possible airborne distribution
	Junin–Argentine hemorrhagic fever	*Calomys musculinus*	
	Machupo–Bolivian hemorrhagic fever	*Calomys callosus*	
	Guanarito virus disease–Venezuelan hemorrhagic fever	*Sigmodon hispidus*	
	Lassa fever	*Mastomys natalensis*	
Bunyaviruses/ hantaviruses	Hantaan virus		Contact with urine, feces, and saliva. May be aerosolized or enter through abraded skin
	Korean hemorrhagic fever virus	Field mice	
	Seoul virus	Urban rats	
	Sin Nombre virus		
	Hantavirus pulmonary syndrome	Deer mice and other rodents	
Puumulavirus	Nephropathia epidemica virus	Voles	
Filoviruses	Marburg virus	Reservoir not clear	Contact with infected monkeys
	Ebola virus	Reservoir not clear	Blood and other personal contact after infection in humans
Poxviruses	Cowpox virus, Monkeypox virus	Cows, monkeys, sheep	Animal skin lesion to abraded human skin
	Contagious pustular dermatitis (orf)		
Herpesvirus	Herpesvirus B	Rhesus monkeys	Saliva by bite or contact
Orthomyxovirus	Swine influenza virus	Pigs	Close contact
Picornavirus	Encephalomyocarditis	Rodents and monkeys	Possible contamination by urine and feces

trialized countries are often imports from developing countries, where exposure of travelers to infected domestic animals is more likely. Molecular techniques, based on differences in viral nucleic acid structure in rabies viruses transmitted in different parts of the world, are often used to determine the source of exposure (Smith et al. 1992). The few cases and intensive study of those that do occur have allowed recognition of unusual sources of infection, such as a transplanted cornea obtained from a cadaver whose death was caused by undetected rabies (Houff et al. 1979).

Zoonoses not involving arthropods are typical of infections produced by arenaviruses and hantaviruses. With both, rodents and other wildlife hosts are responsible for transmission and maintenance of infection. Sometimes the rodents become diseased, but in most cases the infections are inapparent. Humans become involved incidentally and have no further role in maintenance of the chain of transmission. Viruses such as the arenaviruses (Machupo, the cause of Bolivian hemorrhagic fever, and Junin, the cause of Argentine hemorrhagic fever), as well as the hantaviruses (producing Korean hemorrhagic fever and the hantavirus pulmonary syndrome in North America) are limited geographically by the area ranged by the rodents primarily infected. Human-to-human transmission is rare; most human infection appears to result from exposure to rodent urine heavily contaminated with virus, and possibly other animal products such as feces or saliva (Peters et al. 1974; Mercado 1975). The rodents often live in or near dwellings, and humans may be exposed via aerosol or through abraded skin. Increases in frequency of the disease, which, for example, led to the recognition of the hantavirus pulmonary syndrome in southwestern USA, are related to changes in the environment affecting numbers and activities of the rodent host (Hjelle et al. 1994). It is suggested that an overproduction of pine nuts, the rodents' principal food,

led to the emergence of the disease in the Four Corners area of the USA.

Yellow fever and dengue

The term 'arbovirus' was used for many years to describe a large group of enveloped, lipid-containing viruses that had in common transmission by arthropods (Theiler 1957). This diverse group of viruses has many epidemiological features in common (see Flaviviruses; 47, Togaviruses; and 48, Bunyaviridae). The principal vector is the mosquito, although there are important infections involving ticks and other arthropods. Many are also zoonoses, in which the infection is maintained in wild or domestic animals (the reservoirs), humans being involved only occasionally as dead-end hosts. Because of the nature of the vectors and the reservoirs, particular arboviruses are often geographically limited in distribution. Certain mosquitoes cannot exist outside the tropical or subtropical areas, so climate becomes a major determinant, as does other vector behavior, including preferences in multiplication sites, sources of blood meals, and flight distances. The introduction of West Nile virus from the Middle East and subsequent spread throughout much of North America shows that geographic limitations are not absolute (Petersen et al. 2002).

A list of some important arthropod-borne viral infections, according to the geographical area of their occurrence is given in Table 5. Two important infections, both transmitted preferentially by the mosquito *Aedes aegypti*, which can be spread from human to human by the vector, are yellow fever and dengue. Thus, unlike many other arboviruses, dengue and (in this context) yellow fever are not zoonoses. The mosquito is closely associated with human dwellings in urban areas of the tropics and subtropics, but does not persist in areas with cold winter seasons. Urban outbreaks are typical, because infected humans are ready sources for the transmission of viruses to others. In certain regions, outbreaks of the infections are a regular seasonal occurrence. Control of yellow fever was accomplished in many cities of the Americas before availability of insecticides by eradicating the vector from urban areas. Early control of yellow fever transmission made possible the construction of the Panama Canal. With no urban yellow fever, sylvatic or jungle yellow fever was detected in areas without the usual vectors. The same virus caused the disease, which was found to have a zoonotic host, i.e. subhuman primates. It could be transmitted to humans, especially to people working or living in the forests, by hemagogus mosquitoes. *Aedes aegypti* has recently returned to many cities from which it had been eliminated, and, with it, urban outbreaks of yellow fever.

Several vaccines have been developed to control outbreaks of yellow fever and for primary prevention in endemic areas. The most successful, the 17-D vaccine, is a live-attenuated preparation that confers long-term protection.

Dengue is currently the most important arthropod-borne virus because of its widespread distribution in large parts of the tropics and subtropics and the potential there for extensive outbreaks of life-threatening disease. Urbanization in these regions has led to an

Table 5 *Arthropod-borne viruses of global importance and their vectors*

	Diseases	Family/genus	Vector
Tropics and subtropics	Yellow fever	*Flaviviridae/Flavivirus*	*Aedes* and hemagogus mosquitoes
	Dengue	*Flaviviridae/Flavivirus*	*Aedes aegypti* and *A. albopictus*
	Sandfly fever	*Bunyaviridae/Phlebovirus*	Phlebotomine sandflies
American	Eastern, Western, Venezuelan equine encephalitis	*Togaviridae/Alphaviruses*	*Aedes* and *Culex* mosquitoes
	St. Louis encephalitis	*Flaviviridae/Flavivirus*	*Culex* mosquitoes
	California encephalitis	*Bunyaviridae/Bunyavirus*	*Aedes* mosquitoes
	California tick fever	*Reoviridae/Orbivirus*	*Dermacentor* ticks
Eurasian	Tick-borne encephalitis (Russian spring–summer/central European)	*Flaviviridae/Flavivirus*	Ixodid ticks
	Crimean hemorrhagic fever (Crimean–Congo)	*Bunyaviridae/Nairovirus*	*Hyalomma* ticks
	Omsk haemorrhagic fever	*Flaviviridae/Flavivirus*	*Dermacentor* ticks
	Japanese B encephalitis	*Flaviviridae/Flavivirus*	*Culex* mosquitoes
African	Rift Valley fever	*Bunyaviridae/Phlebovirus*	*Culex* and *Aedes* mosquito
	Chikungunya fever	*Togaviridae/Alphavirus*	*Aedes aegypti* and others
	West Nile fever	*Flaviviridae/Flavivirus*	*Culex* mosquitoes
Australasian	Murray Valley encephalitis	*Flaviviridae/Flavivirus*	*Culex* mosquitoes
	Ross River fever	*Togaviridae/Alphavirus*	*Aedes* and *Culex* mosquitoes

increase in the probability of dengue infection because the virus is transmitted by the vector mosquito from one human host to another without the involvement of a zoonotic reservoir. The high concentration of susceptibles in the sprawling cities results in large-scale outbreaks. The vector *A. aegypti* is well adapted to multiplying in the small pools of water that are frequently found in these areas, especially in seasons with heavy rainfall. In its acute form, dengue is debilitating with high fever and deep pain; and infection can result in dengue hemorrhagic fever/dengue shock syndrome (DHF/DDS). These are life-threatening conditions, which affect mainly children. There are four types of dengue virus, and infection with one type produces only partial immunity to another type. The principal hypothesis to explain the pathogenesis of dengue hemorrhagic fever is based on epidemiological observations (Halstead 1970). The disease is widespread when a second outbreak of infection, typically caused by type 2, follows shortly after another outbreak caused by a different type. Reinfection appears to be the common factor; this occurs mainly in children, and maternal antibody may play a role in infants. A number of immunological characteristics of the disease support this hypothesis, although there is some evidence that the syndrome can be produced on initial infection in individuals without maternal antibody (Barnes and Rosen 1974). In recent years, dengue has been spreading, especially in the Americas. This is of particular concern in the USA because *A. aegypti* is present in the southern states.

Other arboviruses

For arboviruses that are principally zoonoses, disease in humans is generally sporadic or occasional. In North America, eastern equine encephalitis (EEE) is an example of an agent that occurs sporadically, during the summer. Many of the infections are inapparent. Symptomatic infection occurs only occasionally, but may manifest as severe encephalitis with residual mental retardation. The reservoir is wild and domestic birds; maintenance of infection does not require either humans or horses, both of which are dead-end hosts. With arboviruses in the temperate zones there is always the question of persistence through the winter (overwintering) during the period when there is no vector activity. Migrating birds infected by the virus winter in areas where mosquitoes are present and are responsible for the continued transmission of the agent. They return, some being infected, in the spring (Lord and Calisher 1970). With other arboviruses there is some evidence that animals in hibernation may serve to overwinter the virus (Reeves 1974).

In the Eurasian land mass, tick-borne encephalitis (TBE), also called Russian spring–summer encephalitis, is an important, though uncommon, sporadic disease associated with forested areas. The reservoir is small mammals and, to a lesser extent, birds; humans moving into sites where transmission is occurring become infected incidentally. Transovarian transmission can take place in ticks in which the virus is passed to the next generation, further maintaining the infection. In contrast, the most important arbovirus of eastern and southeast Asia, Japanese encephalitis, may be responsible for large numbers of cases of relatively severe encephalitis in humans. This disease is mosquito transmitted and occurs in rice-growing regions which generally have a high mosquito density. The principal reservoir is pigs, also common in the region. Because vector control in these areas has been difficult, emphasis has been placed on vaccination.

VIRUSES AND CHRONIC DISEASES

Persistent infection is well documented for many DNA viruses and some RNA viruses. The herpesvirus group is well known for producing persistent infections, for example recurrent cold sores or genital ulcers caused by herpes simplex virus and herpes zoster due to varicella-zoster virus. The retroviruses, including HIV, are also characterized by long-term chronic infection. It is difficult to establish the role of various viruses to late, seemingly unrelated, events such as the development of cirrhosis and primary hepatocellular carcinoma (PHC) or carcinoma of the cervix. Relating these conditions to viral infections requires the application of epidemiological study designs. For hepatitis B and the production of primary hepatocellular carcinoma, the studies were mainly conducted in Taiwan, where there is a combination of high prevalence of chronic infection and a health care system that allowed a longitudinal study of health care workers. A problem in any of these evaluations is the long time between the infection, which may have been acquired perinatally, and development of the tumor, which can occur many decades later. Demonstration of viral antigen in the tumor is of help, but is not conclusive proof of etiology where the population has a history of widespread infection with the agent. The major epidemiological evidence for etiology has come from a series of case–control and cohort studies that noted a strong association between the persistent infection and primary hepatocellular carcinoma even after controlling for potential confounding variables (Beasley 1988). Similar work is now underway to investigate the link between hepatitis C and PHC.

Epidemiological approaches have also provided evidence of involvement of certain types of papilloma virus in carcinoma of the cervix (Papillomaviruses). Descriptive epidemiological studies have long suggested that an infectious entity, probably sexually transmitted, was involved in etiology. Attention was first focused on behavioral differences and on herpes simplex virus. Case–control studies revealed that herpes anti-

body titers were higher in people with tumors than in those without (Rawls et al. 1970). It was possible to identify viral components in excised tumor, and other factors seemed to confirm the relationship. However, the link was not well sustained in studies controlling for confounding factors, such as sexual activity. When it became easier to work with papillomaviruses, epidemiological studies confirmed the specificity of the association with certain types. Moreover, it was possible to replicate the relationship in different studies in different parts of the world and to demonstrate the strength of the association with the specific papilloma types in question (Reeves et al. 1987). Vaccine control now appears possible (Koutsky et al. 2002).

Research into the long-term consequences of viral infection is very important, because it brings together acute and chronic outcomes affecting the health of populations. Examples include the relationship of EBV to the later development of nasopharyngeal carcinoma and Burkitt's lymphoma. Work in this area is diverse, and ranges from efforts to relate acute respiratory infection to later chronic bronchitis and emphysema to studies attempting to relate infectious agents to the pathogenesis of atherosclerosis. All these investigations must use appropriate epidemiological methods, especially as these techniques are a recognized component of other investigations of risk factors for chronic disease.

INTRODUCTION – THE UNIVERSAL SYSTEM OF VIRUS TAXONOMY

The *Universal System of Virus Taxonomy* has been developed to its present state by the International Committee on Taxonomy of Viruses (ICTV) through a series of seven reports (see The classification of vertebrate viruses), the most recent of which was published in 2000 (van Regenmortel et al. 2000) and an eighth report is reaching completion. The system of taxonomy adopted by the ICTV is sufficiently flexible to withstand the stress of the continual discovery of new viruses from an ever-increasing diversity of host organisms. A hierarchy of five taxa, ranked as orders, families, subfamilies, genera, and species, has been developed. Taxonomic categories below the species level, such as subspecies, strains, variants, genotypes, etc., are not included in this taxonomy and are defined according to the practical needs in each particular field. The concept and definition of the category of virus species is central to the structure of the taxonomy, and the nature of the virus species is discussed separately in The classification of vertebrate viruses.

The highest taxon, the order, comprises a group of families that have certain features in common. In the 7th Report of the ICTV only three orders are recognized. The taxon below the order is the family and 68 families are recognized at present. As yet only nine of these 68 families have been grouped into each of the three orders. However, it is anticipated that the number of orders will increase in parallel with refinement of the methods of characterization of viruses. Orders are designated by names with the suffix *-virales,* families by the ending *-viridae*, and sub-families by the ending *-virinae*. The first order described in virus taxonomy was the order *Mononegavirales,* which contains the families of nonsegmented single-stranded negative-sense RNA viruses (Pringle 1991, 1997; Pringle and Easton 1997). The other orders currently recognized are the order *Caudovirales*, comprising the three families of tailed phages – *Myoviridae*, *Siphoviridae*, and *Podoviridae* (Maniloff and Ackermann 1998) and the order *Nidovirales* comprising the positive-sense RNA viruses with nested-set genomes – the families *Coronaviridae* and *Arteriviridae* (see The order *Nidovirales*).

The orders *Mononegavirales* and *Nidovirales* were established to embrace families of viruses exhibiting similar features of genomic organization and replicative strategies. In the case of the order *Caudovirales*, different criteria were required since any preexisting phylogenetic relationships were obscured by a combination of great geological age, large population sizes, and extensive horizontal gene transfer. Nonetheless, relationships are still evident in respect of common aspects of morphology, replication, and assembly, which can be utilized to provide an operationally useful classification. This emphasizes a fundamental aspect of the *Universal System of Virus Taxonomy*; namely, it is hierarchical and consistent with phylogenetic relationships but not

dependent on them. To some extent this is exemplified also in the case of the order *Mononegavirales*, which was established initially to accommodate three families (*Filoviridae*, *Paramyxoviridae, Rhabdoviridae*) with clear phylogenetic links, and subsequently expanded to include a fourth family (*Bornaviridae*) on the basis of similar genomic organization rather than close phylogenetic relationship. The following list presents the current taxonomy of the order *Mononegavirales*. The convention is now that all taxonomic names, including those of virus species, should be rendered in italics with an initial capital letter when used in a taxonomic context. The names can be used without italics in other contexts.

Bornaviridae
- *Bornavirus*
  - *Borna disease virus*

Filoviridae
- *Marburgvirus*
  - *Lake Victoria marburgvirus*
- *Ebolavirus*
  - *Zaire ebolavirus*

Paramyxoviridae
- *Paramyxovirinae*
  - *Avulavirus*
    - *Newcastle disease virus*
  - *Henipavirus*
    - *Hendra virus*
  - *Morbillivirus*
    - *Measles virus*
  - *Respirovirus*
    - *Sendai virus 1*
  - *Rubulavirus*
    - *Mumps virus*
- *Pneumovirinae*
  - *Pneumovirus*
    - *Human respiratory syncytial virus*
  - *Metapneumovirus*
    - *Turkey rhinotracheitis virus*

Rhabdoviridae
- *Cytorhabdovirus*
  - *Lettuce necrotic yellows virus*
- *Ephemerovirus*
  - *Bovine ephemeral fever virus*
- *Lyssavirus*
  - *Rabies virus*
- *Novirhabdovirus*
  - *Infectious hematopoietic necrosis virus*
- *Nucleorhabdovirus*
  - *Potato yellow dwarf virus*
- *Vesiculovirus*
  - *Vesicular stomatitis Indiana virus*

THE ORDER *MONONEGAVIRALES*

Background

The order *Mononegavirales* was established to accommodate all known viruses with nonsegmented negative-sense single-stranded RNA genomes as indicated by the derivation of the name (mono – single, nega – negative-sense, -virales – viruses). Initially that comprised viruses classified in the families *Filoviridae, Paramyxoviridae*, and *Rhabdoviridae*. The features that distinguished these three families were predominantly morphological and biological. Later, molecular characterization of *Borna disease virus* (the type species and sole representative of the family *Bornaviridae*) revealed that this virus possessed a nonsegmented, negative-sense single-stranded RNA virus genome (De la Torre 1994; Schneemann et al. 1995). It differs substantially from the other three families in several respects, the most fundamental being the intranuclear site of transcription and replication. Entry by receptor-mediated endocytosis is followed by transport of viral ribonucleoprotein to the nucleus where transcription and replication occur. The features common to the four families are listed in Table 1, and the characteristics which distinguish each family are listed in Table 2. (Detailed descriptions and references can be found in .)

Table 1 *Common properties of the members of the order* Mononegavirales

Common properties
Negative-sense nonsegmented single-stranded RNA in the virion
Conservation of gene order
Virion-associated RNA polymerase mediates transcription and replication
Genome transcribed into 6–10 discrete mRNAs from a single 5′-terminal promoter, with the exception of *Borna disease virus* where two primary transcripts are post-transcriptionally processed by the host-cell mRNA splicing machinery
Replication occurs by synthesis of a complete positive-sense RNA antigenome
Nucleoprotein is the functional template for the synthesis of replicative and mRNA
Independently assembled nucleocapsids are enveloped at the cell surface at sites containing virus proteins, except in the case of *Borna disease virus*
All cytoplasmic, except viruses in the genera *Bornavirus* and *Nucleorhabdovirus*
Gene boundaries marked by an end/intergenic/start configuration in all except *Borna disease virus*
None exhibit genetic recombination
Occur in invertebrates, plants and vertebrates

Table 2 *Characteristic features of the four families of the order* Mononegavirales

Family *Bornaviridae*
Spherical particles of 90 nm diameter, with 50–60 nm diameter electron dense core, and outer membrane with 7 nm-long spike projections
Nuclear
Spherical 50–60 nm diameter nucleoprotein core
Genome size: 8.9 kb
Six major open reading frames encoding presumptive 3′-NP (p40)-P (p24)/NS? (p10)-M (p16)-G (p56)-L (p180). Complex pattern of mRNA transcription involving 3 initiation sites and 4 termination sites, mRNA splicing at two introns
Wide host range, horses and sheep regarded as main natural hosts. Associated with neurological disease and behavioural abnormalities
Family *Filoviridae*
Filamentous forms with branching, sometimes U-shaped, 6-shaped or ring-shaped. A unique diameter of 80 nm and varying lengths extending up to 14 000 nm, with spike projections of 10 nm approximately. Infectious particle length is 790 nm for Lake Victoria marburgvirus and 970 nm for Zaire ebolavirus
All cytoplasmic
Helical nucleocapsid, 50 nm diameter, with an axial space of 20 nm diameter and a helical periodicity of 5 nm approximately
Genome size: 18.9–19.1 kb
Seven proteins are encoded in the genome in the order 3′-NP (nucleoprotein)-VP35 (phosphoprotein)-VP40 (matrix protein)-GP (glycoprotein)-VP30(?)-VP24(?)-L (polymerase)-5′. Most genes are separated by nonconserved intergenic sequences, but some genes overlap in a highly conserved pentamer junction region
Biology enigmatic: only two antigenically unrelated viruses known; transmitted by the bloodborne route; restricted to primates; reservoir species unknown
Family *Paramyxoviridae*
Pleomorphic, some roughly spherical, 150 nm in diameter, filamentous forms common in some. All cytoplasmic
Helical nucleocapsid; 13–18 nm diameter, 5.5–7 nm pitch
Genome size: all in the range15.4–15.9 kb, with the exception of the 18 kb of the recently discovered *Hendra virus* and *Nipah virus*
The family comprises two phylogenetically distinct subfamilies; the genome size of viruses in the sub-family Paramyxovirinae conforms to 'the rule of six' (i.e. the nucleotide number is divisible by six), whereas this rule does not apply in the subfamily Pneumovirinae
Seven to nine proteins are encoded in the Paramyxovirinae (of which two to four are derived from overlapping reading frames in the *P* gene), and 9 to 11 in the Pneumovirinae, The virion proteins common to all genera are three nucleocapsid–associated proteins (N or NP, P and L), three membrane-associated proteins (M, G or H or HN, and F). Variable proteins include several non-structural proteins (C, NS1, NS2), a cysteine-rich zinc-binding protein (V), a small integral membrane protein (SH), and a transcription processivity protein (M2). Genes non-overlapping except in the case at the M2/L junction in some pneumoviruses
Found only in vertebrates; no arthropod vectors known. Horizontal transmission, mainly by the airborne route. Predominantly associated with respiratory infections
Family *Rhabdoviridae*
Bullet-shaped or bacilliform; 100–430 nm in length and 45–100 nm in diameter. Surface spikes 5–10 nm in length × 3 nm in diameter
Helical nucleocapsid, 50 nm diameter, unwinding to helical structure of 20 × 700 nm (VSV)
Cytoplasmic with the exception of plant viruses of the genus Nucleorhabdovirus, which multiply in the nucleus and form nuclear inclusions
Genome size: 11–15 kb
Generally have five structural proteins (3′-N-P-M-G-L-5′) plus an additional presumptive non-structural protein in some. Exceptionally, members of the genus Ephemerovirus have up to ten genes encoding glycoproteins of uncertain function
Wide host range, different species infect plants, invertebrates and vertebrates. Some multiply in invertebrates and plants, some in invertebrates and vertebrates, but none in plants and vertebrates. May be vertically transmitted in arthropods (Sigman virus), otherwise transmitted horizontally

General properties

Conventional transmission electron microscopic analysis shows that the virions are large enveloped structures with a prominent fringe of peplomers, 5–10 nm long and spaced 7–10 nm apart, in all except the *Bornaviridae*. The morphologies are variable, but in general distinguish the families. Virion Mr is 300–1 000 × 10^6. S_{20W} is 550–1 045 (plant rhabdoviruses have larger S_{20W} values). Virion buoyant density in CsCl is 1.18–1.22 g/cm^3. Virus

infectivity is rapidly inactivated by heat treatment at 56°C, or following UV- or X-irradiation, or exposure to lipid solvents.

Virions contain one molecule of linear, non-infectious, negative-sense, single-stranded RNA, 8.9–19 kb in size, (M_r of 3–5 × 10^6), which comprises about 0.5–2.0 percent of the particle weight. The viral RNA lacks a capped 5′ terminus, or a covalently associated protein. The 3′ terminus of viral RNA lacks a poly(A) tract. The immediate 5′ and 3′ terminal regions exhibit inverse complementarity, and there are conserved motifs in the terminal regions of all four families. Full-length positive-sense (anti-genomic) RNAs are found in infected cells. The genome comprises a linear sequence of genes, with limited overlaps in some viruses, and with short terminal noncoding regions. There are conserved motifs in the transcription start and end signals in all families and the intergenic regions, which lie between the transcribed genes, range from two to several hundred nucleotides. Exceptionally, genetic information may be encoded in additional reading frames in the *P* genes of respiroviruses and morbilliviruses. Splicing of some mRNA and overlapping start/stop signals are characteristic of bornaviruses.

There are a limited number of proteins in relation to the large particle size. The 5–7 structural proteins comprise envelope glycoprotein(s), a matrix protein, a major RNA-binding protein, other nucleocapsid-associated protein(s), and a large molecular weight polymerase protein, plus in some viruses, several additional nonstructural proteins, which may be phosphorylated. The glycoproteins may have a covalently associated fatty acid proximal to the lipid envelope. The matrix protein is nonglycosylated in all except the bornaviruses in which it is *N*-glycosylated and expressed on the surface of virions and may function as an attachment protein. Enzymatic activities associated with the virions may include RNA polymerase, polyadenylate transferase, mRNA transferase, and neuraminidase.
